2. Inclusion of water flow as a driving agent of soil development, making pedon models suitable to simulate consequences of global change;
3. Mechanistic process description: the physical laws in these models reduce the risk of unsound extrapolations in case of extreme boundary inputs (e.g., climate scenarios) when compared to empirical models.

Weak points of current pedon models are:

1. Assumptions on a constant volume of compartments, which limits situations with volume change (weathering, strong argillo- and bio-turbation) and restricts tillage land use scenarios;
2. Absence of redox processes;
3. Runtime.

Focus on landscape

As opposed to detailed storage and fluxes of materials over the full soil depth in the profile models, landscape evolution models mainly consider the change in a landscape's shape, i.e., elevation due to material redistribution (Fig. 4) at the soil surface. The simplest model (assuming no tectonic change) can be written as:

$$\frac{\partial z}{\partial t} = -\nabla q \quad (1)$$

where z is elevation [L] and q is material flux [$L^3 T^{-1}$], and ∇ is a partial derivative vector over space. This model is used widely in geomorphology studies, yet it neglects soil as part of the system. This problem was addressed by Carson and Kirkby and later by Dietrich et al. (see Minasny et al., 2015) where soil needs to be weathered first from bedrock before it can be transported. The model is written as:

$$\frac{\partial h}{\partial t} = \frac{\rho_r}{\rho_s} \frac{\partial e}{\partial t} - \nabla q \quad (2)$$

Fig. 4 Conceptual model of processes in landscape evolution. h is soil thickness, q are fluxes and W are weathering zones. Modified after Dixon and von Blanckenburg (see Minasny B, Finke P, Stockmann U, Vanwallieghem T and McBratney A (2015) Resolving the integral connection between pedogenesis and landscape evolution. Earth-Science Reviews 150: 102–120, modified Fig. 1b, p.104).

where h is soil thickness [L], e is the boundary between soil and bedrock [L], ρ_s is the density of soil [M L^{-3}] and ρ_r is the density of rock.

The term for material flux can be further decomposed into soil erosion q_s (removal of soil from the surface) and soil transport q_d (the transport of soil) (Willgoose, 2018)

$$\frac{\partial h}{\partial t} = \frac{\rho_r}{\rho_s} \frac{\partial e}{\partial t} - \nabla q_s - \nabla q_d \quad (3)$$

This type of rudimentary model was explored by Minasny and McBratney (Minasny et al., 2015) where the soil evolution in a landscape can be simulated realistically. This basic model combines three processes: weathering, surface soil erosion and transport of soil materials downslope.

Weathering

Weathering functions of rock to soil $\partial e / \partial t$ have been conceptualized, such as the weathering of rock to soil as an exponential decline with soil thickness:

$$\frac{\partial e}{\partial t} = -P_0 \exp(-kh) \quad (4)$$

where P_0 [L T^{-1}] is the potential weathering rate of bedrock, and k [T^{-1}] is an empirical constant. This model describes the weathering of rock that slows down with increasing soil thickness due to the decrease in temperature amplitude and reduction in water infiltration. Another conceptual model is the humped function of Humphreys and Wilkinson (Minasny et al., 2015) which hypothesizes that there is an optimum soil thickness for maximum soil production. Thus, soil production is not maximal at zero thickness as there is considerable instability in reaction and water is not available to accelerate the process.

Real world measurement of soil production only started with the availability of terrestrial cosmogenic nuclide (TCN) dating (Nishiizumi et al., 1991). Heimsath and coworkers (Minasny et al., 2015) measured cosmogenic nuclides of the rock–soil interface and defined rates of soil production where soil thickness is in a steady-state condition between production and erosion. There is a distinction between the rate of soil weathering and that of soil production. The weathering rate defined in pedology includes weathering of parent materials and soils due to physical, chemical, and biological processes. In contrast, the rate of soil production refers to the conversion of consolidated bedrock to soil, which results in thickening of the soil profile.

Stockmann and coworkers (Minasny et al., 2015) found that although rates of soil production vary across studies from different environments, they show an exponential decline with increasing soil thickness. And soil production in Australia appears to be similar in range to that in other parts of the world. Therefore, they were able to derive a global rate of (mm kyr^{-1}) soil production:

$$e/t = 114 \pm 11 \exp(-2.05 \times h) \quad (5)$$

where h is soil thickness in mm. Nevertheless, the production function can be defined to vary spatially (Saco et al., 2006 in Minasny et al., 2015) and should be expected to relate to properties of the local climate. Recent models now distinguish between the weathering of soil (W_{soil}), which includes chemical weathering and saprolite weathering ($W_{\text{saprolite}}$). The soil production function can be equated to saprolite weathering. In models that use this distinction, the thickness of soil and saprolite are simulated at each location.

Erosion and soil flux

In the simplest form, soil erosion (∇q_s) is a power law of slope steepness and upstream area (termed the stream power approach, Tucker and Hancock, 2010). Common refinements include the impact of sediment as both abrading agent and protector of bedrock (Whipple et al., 2000). More advanced models now use cellular-automata where the landscape can be finely discretized in 3-D (Davy and Lague, 2009). Transport of materials can be modeled explicitly in each voxel, creating a more realistic landscape that respects mass-balance.

Focus on soilscape

Recent soilscape evolution models try to combine the features of pedon-scale and landscape evolution models by incorporating both pedogenic and geomorphic processes. The potential advantage of such models is that they allow exploration of the myriad of feedbacks between soil formation and landscape evolution. A key downside is the need to deal with multiple soil components (e.g., multiple texture classes, organic matter pools, bulk density) in both vertical and lateral dimensions. This places large demands on computer memory and processing power. The first soilscape evolution model, MILESD (Vanwalleghe et al., 2013) dealt with this problem by choosing master soil horizons (A, B, C) for its vertical discretization rather than thinner (and more numerous) layers. These horizons would change in thickness over time, depending on the rates of processes that affected soils in different landscape positions. Choosing soil horizons is additionally advantageous because it allows the use of large sets of empirical data based on soil horizonation for model calibration and validation. MILESD was used to simulate soil–landscape development of a catchment in Australia, with simulations starting from a homogenous soil across a hypothetical landscape. Simulations resulted in a distribution of soils across the landscape (virtual catenas) that corresponded to expectations (Fig. 5, taken from Vanwalleghe et al., 2013).

Fig. 5 Evolution of soil horizons in four different landscape positions, simulated with MILESD. Reproduced from Minasny B, Finke P, Stockmann U, Vanwallegghem T and McBratney A (2015) Resolving the integral connection between pedogenesis and landscape evolution. *Earth-Science Reviews* 150: 102–120, Fig. 7, p.104.

A downside of simulating horizons explicitly is the lumping of much soil variation within horizons, and the imposition of one set of soil horizons over the entire landscape, whereas in reality many different sets of horizons may exist in different landscape positions.

A successor model to MILESD, Lorica (Temme and Vanwallegghem, 2015), uses vertical discretization in layers thinner and more numerous than horizons that can vary in thickness in one temporal and three spatial dimensions as a result of pedogenic and geomorphic processes. Lorica also included further detail in the representation of erosion and deposition by merging a transport- and detachment-limited process (Davy and Lague, 2009) with grainsize specificity (Hjulstrom, 1935). The main benefit of these smaller layers that change thickness in response to the erosion, deposition and translocation of the materials in them is in avoiding the loss of information that would follow from fixed layer thickness (see above).

Both MILESD and Lorica mostly run at annual timescales and therefore need extensive calibration to be able to simulate pedogenic and geomorphic processes that occur at much smaller timescales. In addition, even in Lorica, layers are in general currently too thick to use the Richards equation for waterflow—even if computational requirements are met. As a result, soil hydrology is essentially absent and soil hydraulic parameters (such as the saturated water content) are hardly used. In particular, the promise of sub-surface lateral waterflow simulations remains elusive (Van der Meij et al., 2020). The benefit of that absence is that the pedogenic development at each location in the model can be calculated in parallel since locations do not depend on their neighbors other than through geomorphic processes.

A step towards a monthly consideration of surface hydrology, which is intended to enable more detailed representation of soil hydrology was recently made by Van der Meij et al. (2018). Their model HydroLorica, an adaptation of Lorica, uses different timescales to simulate realistically landscape-scale variation in infiltration rates, vertical subsurface waterflow and hence rates of some pedogenic processes (Fig. 6). This is a precondition for improving soil hydrology, particularly for subsurface lateral waterflow.

Despite the computational shortcomings that currently limit the further development of four-dimensional soilscape evolution models, their value for exploring different scenarios of climate and land use change is already clear. Van der Meij et al. (2020), for instance, used HydroLorica to show the development of natural and used landscapes under a range of climates leading to grassland and forest cover, with simultaneous resolution of the changes in landscapes due to erosion, tillage and tree fall, and the changes in soils due to erosion, tillage and translocation.

Fig. 6 Simulated clay content in an undulating transect, showing the impact of dealing with hydrology at monthly resolution and the resulting spatially variable infiltration and clay translocation. Reproduced from Van der Meij WM, Temme AJAM, Lin HS, Gerke HH and Sommer M (2018) On the role of hydrologic processes in soil and landscape evolution modeling: concepts, complications and partial solutions. *Earth-Science Reviews* 185: 1088–1106, Fig.7 p.1098.

Space–time boundary conditions for soilscape models

Initial condition

The initial condition comprises values of all state variables, often stocks, presented in the soil(-scape) model at the beginning of the simulation period, both with depth and spatially. Models with high process detail usually require more state variable values at $T = 0$ than simpler (or empirical) models. Table 1 gives some examples of state variables and also names important variables related to transport of, for example, water, heat, soil mass that are based on the initial state variables.

The importance of correct values of initial state variables depends on various factors:

- Process dynamics: Highly dynamic processes will quickly render the initial value less important because a new steady state may be reached rapidly;
- Model sensitivity to changes in these state variables;

Table 1 Examples of state variables in soilscape and pedon models that must be initialized.

State variables input at $T = 0$	Pedon models	Soilscape models
<i>At pixel/site level</i>		
Elevation and derivatives (e.g., slope)	–	TTLEM ^a , HydroLORICA ^b
Soil depth	–	SSSPAM ^c , mARM3D ^d , TTLEM ^a , HydroLORICA ^b
Vegetation	SoilGen ^e , Witch-Aspects ^f	HydroLORICA ^b
<i>Per depth segment</i>		
Grain size distribution	SoilGen ^e , Witch-Aspects ^f	SSSPAM ^c , mARM3D ^d , TTLEM ^a , HydroLORICA ^b
Bulk density of soil (and rock) and segment thickness	SoilGen ^e , Witch-Aspects ^f	TTLEM ^a , HydroLORICA ^b
Vertical transport-related parameters	SoilGen ^e , HP1 ^g	HydroLORICA ^b
Lateral (surface) mass transport parameters	–	HydroLORICA ^b
Organic carbon content	SoilGen ^e , Witch-Aspects ^f	HydroLORICA ^b
Cations and anions in solution	SoilGen ^e	–
Cations at exchange complex and CEC	SoilGen ^e , Witch-Aspects ^f , HP1 ^g	–
Minerals (contents and stoichiometry)	SoilGen ^e , Witch-Aspects ^f	–
Volumetric water content	SoilGen ^e , Witch-Aspects ^f , HP1 ^g	–
Temperature	SoilGen ^e	–

- Simulation scenario: The dynamics at the upper soil boundary, duration of the simulation period and the occurrence (or not) of soil rejuvenation by erosion or deposition bringing fresh parent material close to the surface.

The initial condition represents a status in the past, therefore, it must be obtained by reconstruction if a real soil(-scape) is to be simulated, or by definition, in the case of a virtual situation. For soil status variables, inventories of the parent material are often the data source. These may comprise properties of the C-horizon, or that of shallow bedrock as derived from soil and geology maps and associated information systems. When the initial situation is an already developed soil and not simply the parent material, reconstruction of the properties is more complex, associated with uncertainty, and will use vertically and or laterally distributed soil data.

Similarly, the initial topography can be represented by landscapes resulting from a reconstructed geological history. Heimsath and coworkers (Minasny et al., 2015) and Campforts et al. (2016) used inventories of terrestrial cosmogenic nuclides to reconstruct soil production and redistribution spatially that could be used for landscape reconstruction. In other cases (e.g., Campforts et al., 2017) the current landscape was used as the initial topography.

Time-variant upper boundary condition

Changes at the upper boundary of the soil(-scape), i.e., the soil–atmosphere interface, influence matter or energy transfers into the modeled system. These inputs clearly relate to the factors of soil formation (Table 2). A notable difference between pedon and soilscape models is that erosion and deposition are inputs in the (1-D) pedon models, but they are the calculated results of surface mass redistribution processes in the soilscape models.

Slope and exposition are usually time-invariant in pedon models, but may change over time in soilscape models due to surface mass redistribution. In both cases they are not true boundary conditions but may still vary over time.

As a consequences of boundary inputs, rates at which soil processes take place are influenced. For instance, organic matter decomposition rates are influenced by water content and temperature, chemical reaction constants are modulated by temperature changes, and so on.

The importance of time-variant upper boundary conditions is that they allow the reconstruction of soil development to the present using reconstructed changes in soil forming factors, and also enable the calculation of how future global change will affect the soil(-scape). This is conditional on the processes covered by the used model (Minasny et al., 2015).

There is a rich variety of methods to obtain upper boundary inputs (Table 3). Three main cases can be identified:

1. Boundary conditions are reconstructed using proxies.

Proxies are measurable variables in soils or sediments that can be dated, e.g., via a depth–age model in the sampled material. The ages are obtained in most cases by ^{14}C dating, OSL (optically stimulated luminescence) dating or radioactive decay. Proxies can be botanical (pollen diagrams, diatoms, macrofossils, tree rings), zoological (ostracods, molluscs, chironomids) and chemical (magnetic susceptibility, stable isotopes), and are transformed to the target variable using knowledge on ecological niches or correlation to known values. Proxies can be combined to obtain better estimates of the target variable (e.g., Bos et al., 2017), and are often mapped by space–time interpolation during the estimation process as sampling sites and application sites are usually not the same (e.g., Davis et al., 2003).

Table 2 Time-variant upper boundary conditions in soil(-scape) models.

Upper boundary conditions	Processes influenced
Climate	Temperature Heat flow, correction of chemical equilibria, physical weathering Precipitation: water Water flow Precipitation: solutes Solute flow Evaporation Evapotranspiration
Organisms	Vegetation Biomass production, C-turnover, CO ₂ -diffusion, solute uptake Fauna Bioturbation Human influence: Fertilization Solute flow and -uptake Irrigation Water flow, biomass production Tillage Heat/water/solute flow modification Crop protection Biomass production
Relief	Slope Runoff Exposition Heat/water/solute flow modification
Mass redistribution	Erosion Removal of topsoil, texture grading Deposition: texture Chemical dissolution/precipitation, C-cycling, clay migration Mineralogy Mineral weathering and new formation Solute/exchange chemistry Chemical equilibria, cation exchange equilibria Change of boundary conditions All of the above
Time	

Markings  indicate influence by global change.

Table 3 Four examples of proxy- or model-reconstructed boundary conditions for soil models.

<i>From proxy data source</i>	<i>To</i>	<i>References</i>
Pollen diagrams, diatom assemblages	Vegetation; precipitation; potential evapotranspiration; summer- and winter temperature	Davis et al. (2003)
Magnetic susceptibility and remanescence	Precipitation	Maher and Thompson (1994)
<i>From earth system model</i>	<i>To</i>	<i>References</i>
HadGEM, IPSL-CM5A, MIROC-ESM-CH + Orchidee	Temperature; precipitation Net primary production	Keyvanshokouhi et al. (2019)
LOVECLIM	Natural vegetation; monthly average precipitation, potential evapotranspiration, temperature	Finke et al. (2018)

2. Boundary conditions are constructed using models of other earth system compartments.

Earth system models describe a larger part of this planet than the soil and therefore are useful to obtain inputs at the soil(-scape) upper boundary. In contrast to proxies, they can be used for both reconstruction (e.g., paleoclimatic models; Finke et al., 2018) and projection (e.g., Keyvanshokouhi et al., 2019) studies.

3. Boundary conditions are constructed using historical documents.

In some cases, and mostly for land use reconstructions, historical maps, observations and documents can be consulted to obtain boundary conditions but their temporal range is usually restricted to a few centuries or less.

Time-variant lower boundary conditions

While the upper boundary of a modeled soil system is the soil–atmosphere interface, the depth of the lower boundary of the system can be set in various ways, for instance (i) at the interface between unconsolidated (i.e., sediment, regolith) or consolidated material (i.e., bedrock), or (ii) at arbitrary, fixed depths. Over pedogenetic timescales, the interface between regolith and bedrock may move downwards due to soil production or sediment addition and it may move upwards due to erosion and denudation processes. This is a complication in terms of setting up a model, and therefore often a fixed depth is chosen that is large enough to absorb the effects of erosion and to include the A and B horizons minimally.

The most important boundary conditions that need to be specified are related to the hydrology and temperature of the modeled system.

Common bottom boundary conditions for water flow are: (i) the bottom flux is defined by a constant or variable water table, (ii) free drainage (deep or no groundwater table; the bottom flux is restricted by the hydraulic conductivity of the lowest compartment at unit hydraulic head gradient), (iii) zero drainage (impermeable layer).

In case (i), input of variation in the water table over time is required. This may be relevant when agricultural water management is implemented, e.g., by artificial drainage. Another way to input variation in the water table is using option (iii) where the layer at the average water table depth in a particular period is assigned a low permeability (e.g., Zwertvaegher et al., 2013). This is one way to couple a 3-D groundwater model to a 1-D-pedon model taking regional groundwater variations into account.

Most studies apply free drainage at the lower boundary though some examples exist where the bottom boundary condition switches between free drainage and zero drainage as a function of the aridity of the climate (e.g., Finke and Hutson, 2008).

Common bottom boundary conditions for heat flow are: constant temperature, a zero heat flux condition, or a heat reservoir. The heat reservoir is the most likely to be applied, as it dampens but does not exclude temperature change in the deep soil layers, though when modeling soil development in permafrost soils other options might be considered.

Heterogeneity

Heterogeneity can partly be accommodated by setting the initial conditions to reflect lateral and vertical variations in parent materials, but in some cases new heterogeneity can be caused by disturbances during a soil(-scape) simulation, and then affect the boundary conditions. Examples are:

- Tectonic and volcanic events. For tectonic events, at the top boundary, elevation and slope may respond, causing mass movements (Coulthard and van de Wiel, 2013). At the bottom boundary, mainly the water flow regime is affected. Volcanic events are largely unexplored with models, but river blockades and the formation of temporary lakes would have to be accounted for (Van Gorp et al., 2016).
- Interventions in the local and regional water management. At the top boundary, an irrigation boundary condition may become active. At the bottom boundary, mainly the water flow regime is affected when artificial drainage conditions are implemented.
- Permafrost thawing. At the bottom boundary, both the water flow regime and the heat flow regime may be affected once permafrost has disappeared, the active zone deepens or a talik is formed.

Identifying and minimizing uncertainty

Accuracy assessment

All models are associated with uncertainty, and therefore assessment of the accuracy of prediction of its major output variables is essential. Soil development models cover substantial temporal extents, varying between a few decades to millennia. For accuracy assessment, comparisons to field data are needed, which represent the current state of the soil system. Such assessment might not indicate whether all process constants are well-set, as various combinations of these constants might lead to similar accuracies. This problem of non-uniqueness may be partly avoided in two situations:

1. A chronosequence is present.

A soil chronosequence contains soils covering different periods in the climate and land use history. The overall effects of different histories of boundary conditions as well as the duration of soil development are then represented in both soil data and simulation results. Sauer and coworkers (Minasny et al., 2015) assessed model accuracy in a glacial rebound chronosequence in Norway for soil ages between 2100 and 11,050 years and concluded that deviations between various simulated and measured soil variables developed within 2100 years. As an alternative, if the study area includes a climatic gradient this may be used to evaluate model behavior under different boundary inputs. Buried paleosoils with boundary conditions derived from a paleoclimate model may also be used for accuracy assessment.

2. Monitoring data exist over a temporal extent comparable to the temporal autocorrelation length of the soil variable studied. This may be the case for soil organic carbon models that are compared to long-term field experiments.

Minasny et al. (2015) analyzed 29 soil(-scape) development model studies and found that pedon models are more often (11/14) compared to field data than soilscape models (5/15).

Soil and elevation data for calibration and accuracy assessment

Soil(-scape) evolution models can be compared to data on different spatial supports and extents, and can use both legacy data (with known age) and recent data. Soil inventories may be up to 75 years old, therefore, it may be useful to account for their age by selecting model outputs for the same period (e.g., Zwertvaegher et al., 2013) to avoid the possibility that recent land use change is not represented by the soil data.

- Landscape evolution models are frequently compared with digital topographic datasets to assess their validity. This works in two cases: when current landscapes are considered in equilibrium with their tectonic and climatic boundary conditions (in which case models run from a hypothetical starting landscape until they, too, reach equilibrium, Taylor Perron and Hamon, 2012), or when topography is well known for a point in the past as well as in the present (in which case models run from the past topography to the present—rarely the other way around; see work by Temme et al., in Minasny et al., 2015). In both cases, metrics of current day topography are extracted from digital topographic datasets and from model outputs (e.g., using TopoToolbox; Schwanghart and Scherler, 2014), and are then compared.
- Soilscape evolution models can similarly be evaluated with soil maps and digital topographic datasets. Either of the two conditions expressed above would have to be met on the topographic side. When assuming equilibrium, observed soil patterns would additionally have to reflect the developmental endpoint in a landscape in equilibrium with tectonics and climate, to be comparable to simulated soil patterns. When using a well-known starting landscape, soil patterns at that past point in time would also have to be known accurately and used as a boundary condition in the soil-landscape evolution model. A soil map can be used for quality testing of a simulated soilscape after conversion of the soilscape model output to the legend of the soil map. This could be done under the assumption that the soil map is without error by counting the fraction of the area with equal classification in both soil map and modeled soilscape (confusion matrix). However, no examples of such quality tests are yet known. The few known soilscape-soil map comparisons are based on datasets of pedons (e.g., Vanwalleghe et al., 2010; Zwertvaegher et al., 2013). The spatial coverage of such pedon datasets may be increased by one of the many methods under the umbrella of digital soil mapping (DSM), in which case uncertainty of the spatial soil data should be accounted for while testing model accuracy.
- Pedon models can be compared to field data obtained at the simulation locations. Minasny et al. (2015) reported various examples, where the most common soil variables to be tested were clay content, organic carbon content, soil pH, CEC and calcite content (Opolot, 2016).

Calibration

To improve model accuracy, sensitivity studies followed by model calibration can help. Sensitivity studies help to identify the model process constants that are most promising for calibration. There are many methods for sensitivity analysis (cf. Minasny et al., 2015) and the most feasible method largely depends on the computational demands by the soil(-scape) model. Exhaustive sensitivity analyzes, where all combinations of model parameters are explored, are usually beyond computational possibilities. A random sampling of the model parameter space has so far been used instead (e.g., Temme and Vanwalleghe, 2015).

Calibration can be done on a parameter by parameter basis, starting with the most sensitive process parameter and proceeding with increasingly less sensitive parameters. This approach is feasible when the computational demands of the model are high, which is often the case in soil(-scape) development models. More advanced methods (Minasny et al., 2015) that simultaneously vary several (sensitive) process parameters are only feasible with fast models.

Several studies have shown that the quality after calibration shows sensitivity to the boundary and initial inputs over the simulation period. This suggests that calibrated models cannot be transported to different settings. Keyvanshokouhi et al. (2016) showed that uncertainty in estimating the agricultural history of a site affects the quality after calibration and also demonstrated the effect of the uncertainty of the initial soil texture. Ongoing research suggests a strong relation between the (uncertain) dust deposition history and quality after calibration in the Chinese Loess Plateau.

To summarize, in soil development models the quality after calibration is conditional on the accuracy of various boundary and initial conditions. In synthetic scenario studies, these conditions are not reconstructed but defined. Therefore part of the uncertainty is reduced in these studies but at the cost of being relevant for a particular region. In particular, the computationally intensive soilscape evolution models may be restricted to this exploratory model use for the near future.

Outlook

Pedon and soilscape development models will be suitable instruments for evaluating scenarios of global change if they are hydrology-enabled, describe the soil-C cycle and accept land use management as upper boundary conditions. This stage has now been reached for some pedon and soilscape development models. Coupling with climate models has led to realistic scenarios for past (Finke et al., 2018) and future (Keyvanshokouhi et al., 2019) soil development. A necessary next step will be to consolidate this situation by increasing the set of models with this ability, which will increase the competition between such models via model comparison and lead to improvements. The work of the climate modeling community can be used as a template. Useful future activities are model testing on standardized data sets. Additionally, a larger suite of models will enable assessment of the effects of global change on soils in a similar way to that by the climate modeling community: by ensemble modeling. This stage has not yet been reached.

From the perspective of understanding soil–landscape relations, ideally, process-based models would be used to map how soils vary spatially in the landscape. This would remove the empiricity of DSM. Some cases already exist: Bonfatti et al. (2018) tested whether a simple landscape evolution model can predict soil thickness in a valley of the Rio Grande do Sul, Brazil. The results are promising but also have limitations due to erosion processes at short time scales and uncertainty involving soil formation of the area. Lozbennev et al. (2021) used a hydrological model to calculate runoff over the catchment. They found that the simulated runoff alone can explain the variation of the depth of secondary carbonates in soils and the soil taxa. Finke and coworkers (Minasny et al., 2015) used a distributed pedon model to find causes for “noisy” soil–landscape relations in a loess region in Belgium and identified treefalls as the likely source of the noise. The link between DSM and soilscape modeling is becoming closer, as process knowledge is being used increasingly in DSM (e.g., Angelini et al., 2016) and DSM can be used to identify major processes in a particular soilscape (e.g., Baltensweiler et al., 2020).

Abstract

The role of soil in current climate models is reviewed and discussed, with a focus on developments over the last two decades. Soil modeling may be divided into three major parts: simulation of soil hydrological dynamics, soil biogeochemistry and the soil thermal environment. Each of these three major parts is summarized with a brief description of current best practice and developments. Specific issues and modifications relevant to four extreme environments are highlighted: drylands, tropical moist and wet forests, cold regions, and peatlands and wetlands. Finally, current advances in the areas of hyperresolution and coupled model environments are discussed, which we see as the two leading edges of current soil model development.

Glossary

Baseflow Baseflow is here taken to be the lateral outflow from soil summed over all phreatic soil layers (i.e. at and below the water table). Note that *baseflow* here does not refer to the outflow at a particular ‘basal’ level, and also does not refer to the relatively constant minimal flow of a stream or river under low or absent rainfall.

Darcy–Buckingham Law The Darcy–Buckingham Law describes how hydraulic head controls the movement of water in both saturated and unsaturated soils (Henry Darcy published **Darcy’s Law** governing the saturated case in 1856, which Edgar Buckingham extended to the unsaturated case in 1907) (Hillel, 2004).

Groundwater Groundwater is the water held in the **soil phreatic zone**, i.e. the saturated soil zone between the water table and impermeable bedrock (including all water held in rivers, lakes and the ocean) (Fig. 2) (n.b. this is distinct from subsurface-water as defined below).

Inundation Inundation is any water flowing temporarily on the soil surface but not part of a lake or water course. This includes **detention storage**, i.e. water that is in transit as runoff toward a water body.

Peatlands Peatlands are areas with a naturally accumulated layer of dead organic material (peat) at the surface (if peat is still in the process of being formed, it is also termed a **mire**) (Parish et al., 2008).

Ponding Ponding is any stationary water that is temporarily on the soil surface but not part of a lake or water course. This includes **depression storage**, i.e. water occurring in small surface depressions.

Richardson–Richards Equation The Richardson–Richards Equation is the most widely-used equation governing the movement of water in unsaturated soils (Farthing and Ogden, 2017). Note that we follow Raats and Knight (2018) in referring to both authors in the name of this equation: Lewis Fry Richardson and Lorenzo Richards, who published effectively the same equation in 1922 and 1931, respectively.

Soil moisture/soil water Soil moisture / soil water is the water content of the soil profile. Note that we define the soil column to stretch down to impermeable bedrock, therefore this term includes all groundwater (as defined below).

Subsurface-flow Subsurface-flow is the lateral outflow from soil summed over all vadose soil layers. Note that, according to these definitions, the sum of all lateral outflow below the surface is (*Subsurface-flow* + *Baseflow*) (Fig. 3), i.e. $\text{Total Runoff} = (\text{Surface Runoff}) + (\text{Below Surface Runoff}) = \text{Surface-flow} + \text{Subsurface-flow} + \text{Baseflow}$.

Subsurface-water Subsurface-water is the water held in the soil vadose zone, i.e. the unsaturated soil zone between the surface and the water table (Fig. 2) (n.b. this is distinct from groundwater as defined above).

Surface-flow Surface-flow is flowing surface-water. Note that, although it perhaps seems counter-intuitive, for consistency we take the term *surface-water flooding* to exclude river and coastal flooding.

Surface-water Surface-water is the water held above or on the land surface (including overland flow, glaciers and snowpack, but excluding water held in rivers, lakes and the ocean¹).

Terra firme Terra firme (literally *solid ground*) is land that is neither seasonally nor permanently flooded (i.e. away from large wetlands, rivers or lakes). Accepted in English since the 1600s, this term is currently widely used in Brazil (e.g. *terra firme forest*), but was originally used to refer to the mainland territories of the Republic of Venice, Italy.

Water table/Phreatic surface The water table/phreatic surface is the surface below which all fractures, pores and other voids are saturated with water. Under some conditions, a capillary fringe or tension-saturated zone can form immediately above the water table where the soil is saturated with water, yet the water remains under tension.

Wetlands Wetlands are areas that are inundated or saturated by water at a frequency and for sufficient duration to support emergent plants adapted for life in saturated soil conditions (Parish et al., 2008) (n.b. all mires are wetlands, but not all wetlands are peatlands and not all peatlands are wetlands).

Key points

- Soil modeling may be divided into three major parts: simulation of soil hydrological dynamics, soil biogeochemistry and the soil thermal environment
- Each of these three major parts is reviewed and a summary provided of current best practice and developments
- Specific issues and modifications relevant to four extreme environments are highlighted: drylands, tropical moist and wet forests, cold regions and peatlands and wetlands
- Finally, current advances in the areas of hyperresolution and coupled model environments are discussed

Nomenclature

DEM	A Digital Elevation Model (DEM; aka a Digital Terrain Model, DTM) is an elevation map; a representation of the physical topography of a landscape. DEMs are generally derived from Digital Surface Models (DSMs), which are based on remote-sensing data collected by planes, drones and satellites. DSMs follow the highest level of all elements of the land surface (imagine gently laying a sheet over the Earth's surface). A DEM may be derived from a DSM by subtracting anthropogenic surface elements (e.g. buildings, bridges) as well as canopy height (in vegetated areas) and the depths of free water elements existing on the surface (e.g. glaciers, snow; q.v. Fig. 2). However, n.b. because of the relative unreliability of bathymetry data, especially for smaller rivers, and the depth of small water bodies is often not known and thus not subtracted for DEMs follow level L3 only on terra firme (q.v. Fig. 2), and actually follow the surfaces of rivers, glaciers, lakes and oceans elsewhere.
ESM	Earth system models (ESMs) are models that simulate the coupled interactions between the atmosphere, ocean, ice and land surface. Several ESMs are under development around the world and are usually built up in a modular fashion from pre-existing models that simulate individual components.
GEWEX and WCRP	The Global Energy and Water Cycle Exchanges Project (GEWEX) is the core project in the World Climate Research Programme (WCRP) concerned with studying the dynamics and thermodynamics of the atmosphere and interactions with the Earth's surface.

¹It may seem odd to categorize river, lake and ocean water as groundwater rather than surface-water, but this is a consequence of the definition of groundwater being water below the water table (Fig. 2).

ISMC	The International Soil Modeling Consortium (ISMC) aims to integrate and advance soil systems modeling, data gathering and observational capabilities at a global level.
LSM:	Land surface models (LSMs) are the part of Climate Models or ESMs that simulate processes happening at the Earth's surface. LSMs include standalone models as well as the component models of Climate and ESMs that are concerned with the dynamics of the land surface.
SOC and SOCD	Soil Organic Carbon (SOC) (% of dry soil by mass) is the amount of carbon (C) contained in SOM, where $SOC = c_{SOM} * SOM$ (approximately 50% by mass, i.e. $c_{SOM} \approx 0.50$, Pribyl (2010) , where $(1/c_{SOM})$ is the <i>van Bemmelen factor</i>). In a soil layer of depth D (m) it is most usual to quote either SOC or Soil Organic Carbon Density, SOCD (t C/ha), which is defined by $SOCD = SOC * DBD * D * 10000$, where DBD is the dry bulk density of the layer (g/cm^3 or t/m^3) (Rodeghiero et al., 2009).
SOM	Soil Organic Matter (SOM) (% of dry soil by mass) is composed of soil microbes including bacteria and fungi, decaying material from plants and animals, fecal material, and products formed from their decomposition (Campbell and Paustian, 2015).

Introduction

Soil plays a crucially important role in sustaining life on Earth. Many aspects of the complexity of soil and the dynamics of its constituents are well-understood ([Hillel, 2004](#)), but under climate change soil properties are beginning to change, fundamentally affecting their associated dynamics and the services soils provide to humans. In addition, climate change is bringing us into a new era of more frequent climate extremes ([IPCC, 2021](#)) and soils are being affected by large-scale processes that are generally not yet included in soil scientific models ([Kendon et al., 2021](#)). We provide here an overview of the current representation of soil processes in climate models and associated land surface models (LSMs). We identify the dominant soil-related issues that are of concern across the globe, and provide links to data sources and new research that summarize current innovations in this fast-moving field.

Standard soil model components of land surface models

A reliable characterization of the soil in terms of water balance, nutrient status and thermal regime is necessary for the simulation of soil in LSMs ([Fig. 1](#)). Global-scale LSMs calculate soil moisture, soil temperature and other soil variables continually during simulations, tracking also the feedback processes through which soil-mediated fluxes influence the lower layers of the atmosphere (land–atmosphere feedbacks).

The role of the soil profile in land surface models – how deep is a soil profile?

Soil profiles are theoretically taken to extend from the ground surface to impermeable bedrock (Level L1, [Fig. 2](#)). For a spatially-explicit soil simulation model, it is critically important to consider the extent of the model domain. Asking “How deep

Fig. 1 A summary of soil processes of greatest relevance to LSMs and ESMs (Earth system models). Models exist that focus on all parts of this modeling sequence (see the ISMC [Model Portal](#) for a comprehensive list).

Fig. 2 A representation of standard conceptual levels in land surface models (LSMs): L1 is the bedrock surface, L2 is the surface of the shallowest confining layer (whether impermeable or semipermeable), L3 is the ground surface (underneath any free water present at the surface, i.e. glacial ice, solid snow, freshwater or seawater). Note that the water table runs below L3 over most of the land surface (fluctuating in response to rainfall), but is above L3 in rivers, lakes and the ocean because it follows the free water surface when that is above the soil. Level L1 will usually be less than 250 m below the surface, and only exceptionally down to approximately 700 m (Richter and Markewitz, 1995; Shangguan et al., 2017). The section outlined is shown in greater detail in Fig. 3.

is the soil?" is a deceptively simple question (Richter and Markewitz, 1995): the answer can vary greatly because of variation in the definition of "the soil" in different disciplines (Shangguan et al., 2017). Does the soil profile stretch all the way from the ground surface you stand on to the level of impermeable bedrock below? Is weathered rock included? What about an impermeable clay layer a few meters below the ground? If you are standing on leaf litter rather than bare soil, are those leaves part of the soil, too? Is a half-decomposed log nearby (coarse woody debris) also part of the soil? Here, we follow soil science norms and would answer "yes" to all five of these questions.

Most model simulations out of necessity make a practical division of the soil profile into two parts, the upper and lower soil profile:

- (1) *Upper soil profile – A and B horizons – Topsoil and subsoil* (Fig. 3): The upper part of the soil profile is considered to be the part from the ground surface (i.e. Level L3, Fig. 2) down to what is termed the soil simulation lower boundary (SLB). The SLB depth in LSMs is usually relatively shallow (<5 m), which means that at many global locations soil profiles in LSMs are simulated to be deeper than they are in reality (e.g. mountain regions) and in many other locations the direct simulation of soil involves only a small percentage of the material below Level L3. Many studies have shown that model simulations return improved soil flux gradients when finer soil layers, or a greater number of vertical soil layers, are used (e.g., Lekshmi and Arnepalli, 2017; Batelisi et al., 2020).
- (2) *Lower soil profile – C horizon* (Fig. 3): The lower part of the soil profile is considered to be the part from the SLB down to Level L1 (bedrock). In some models, the lower soil is simulated with heightened lateral in/outflow because of the application of a 3-D Richardson–Richards approach that would be too computationally intensive at shallow soil depths. Note, in most biomes the water table fluctuates continually between the upper and lower part of the soil profile, therefore if two different submodels handle the two domains the water table should be able to move realistically between the two within the simulation (Fan et al., 2007).

Fig. 3 An example 1-D soil profile in two neighboring simulated locations, where the soil simulation depth is at level L2 (Fig. 2). Note that if topographic flow directions at the surface are not parallel to flow directions at depth (as illustrated in this example location), then two sets of ancillary flow directions are required for the simulation of water flow in the landscape, with the former calculated from a DEM and the latter calculated from a DEM with soil depths subtracted (q.v. Pelletier et al., 2016; Shangguan et al., 2017). Although variation in soil surface elevation (microtopography) both spatially (i.e., within-gridcell, e.g. thermokarst landscapes and permafrost thaw, Aas et al. (2019)) and over time (e.g. peatland development, Baird et al., 2012) is important in many contexts, this is usually assumed not to affect subsurface flowpaths. The A, B, C and R horizons of a soil profile are closely related to the dynamics of water within the profile (Hillel, 2004), and in modeling frameworks the level L2 generally coincides with the lowest part of the B horizon (subsoil). Note that although some sources separate out an O horizon or humus layer at the upper end of the A horizon, here we include this in A. Similarly, some sources separate out an E Horizon or eluviation layer at the lower part of the A horizon, but we also include this in A. 'Regolith' is most widely used to refer to all unconsolidated rock (i.e. horizons A, B and C together) (although note Pelletier et al. (2016) used the term 'intact regolith' to refer to what we call here the soil C horizon).

Why is the SLB depth not simply fixed at Level L1 to capture the whole soil profile? One answer is historical: LSMs were developed originally as descriptions of the lower boundary layer of climate models, and a few meters of soil were considered sufficient for the most simple representation of the land surface. Second, global data on soil depths were lacking at the time, although this is no longer the case (Shangguan et al., 2017).

A third reason was, and remains, the challenge of simulating semi-permeable or impermeable layers at intermediate depths within the soil profile. The presence of such layers requires soil hydraulic properties to vary with depth in the soil profile simulation to allow the possibility of flow pathways at depth to differ from those at the surface (e.g. Fig. 3). Setting the depth SLB at a point above the surface of the first discontinuity (Level L2, Fig. 2) in theory allows the complications introduced by confining layers to be handled separately from surface soil simulation. Two difficulties arise with this approach, however:

- The effect on the atmosphere of not just the upper soil but also the lower soil profile is now known to be highly significant (Martinez-de la Torre and Miguez-Macho, 2019) and
- Many soils have semi-permeable or permeable layers (aquicludes) very close to the surface (e.g. lenses of ice or taliks in permafrost environments). The 'Australian Evergreen Paradox' provides a clear example of how this can have important implications: the marked dry season of the northern Australian monsoon tropics would lead a standard LSM to predict dominance by deciduous tree species, while in reality the presence of deep water aquifers within the reach of tree roots facilitates widespread dominance by evergreen species (Bowman and Prior, 2005).

Soil moisture model components (hydraulics and hydrology)

Soil moisture is a critically important variable both in the context of land management and scientific theory, and its status is determined by the interdependent processes of ‘soil hydrology’ (water movement within the soil) and ‘soil hydraulics’ (the mechanical behavior of water in the soil physical system), both at the surface and at depth. The soil at any particular location is characterized as a layered column (profile) where water can enter from above and can also enter or leave via a simulated lower boundary (SLB) (see Fig. 2), with profile moisture content determined by the water balance equation at the soil surface (Beven, 2012):

$$\begin{aligned} \text{(Total Water Input to Soil)} = & \text{(Precipitation)} + \text{(Irrigation input)} - \text{(Evaporation)} - \text{(Surface-flow)} \\ & + \text{(Below-surface lateral inflow}^*) - \text{(Below-surface lateral outflow}^*) \\ & + \text{(Capillary rise from below SLB)} - \text{(Drainage at level SLB of the soil)} \end{aligned}$$

*n.b. ‘Below-surface lateral in/outflow’ will correspond to (Subsurface-flow) if SLB is at the water table, or (Subsurface-flow) + (Baseflow) if SLB is at level L1 (Fig. 2).

The flow of water through individual soil layers and the vertical position of the water table are determined from these inputs by applying a similar water balance at each layer, modified to allow upward capillary flow through the application of a soil hydraulic model based on the Richardson–Richards Equation (Clark et al., 2015; Farthing and Ogden, 2017). Soil hydraulic models simulate the soil water characteristic (SWC), which is a relationship between soil matric suction ψ (Pa) and volumetric moisture content θ (cm^3/cm^3) parameterized for each soil in the simulation area (Table 1). These calculations result in an estimate of soil moisture status in each soil layer, water table depth and also surface and subsurface runoff. In organic soils (i.e. soils with a significant O horizon), especially, soil structure is important (Fatichi et al., 2020), therefore it is critical to apply these models carefully to capture reliably the fluxes close to the soil surface (e.g. when macropore or bypass flow is significant).

This water balance approach characterizes the state of the soil surface (including ponding) (Table 1). Runoff production models then produce estimates of surface and subsurface runoff, which may be used to predict the dynamics of flow velocity in local water courses and also any occurrence of inundation.

Current LSMs generally identify a reasonable soil SLB depth (above Level L2, Fig. 2, ideally close to the bottom of the soil’s B horizon, Fig. 3). Two different soil simulation models are applied for the upper and lower soil profiles (i.e. above and below the SLB). Upper soil profile simulators usually assume that lateral subsurface-flow and baseflow are zero so that a 1-D Richardson–Richards equation may be applied. Lower soil profile simulators, however, generally assume that the effects of vegetation (deep roots) are negligible and apply a Boussinesq equation (based on Darcy’s Law) that allows the 3-D dynamics of aquifers to be simulated.

Pedotransfer functions (PTFs) are used to source parameter estimates based on soil profile data (Weihermüller et al., 2021), e.g. from soil profile databases such as UNSODA or EU-HYDI, and are currently a focus of global theoretical development (see the current ISMC Working Group on Pedotransfer functions and land surface parameterization). Although the empirical nature of PTFs is theoretically undesirable and semi-physical PTFs do exist (Zhang et al., 2018), they remain the most practical simulation approach in the context of large-scale LSMs.

Table 1 Models concerned with water flow in or on the soil profile.

	Model
<i>(1) Water flow in the upper soil profile</i>	
Models of the soil water characteristic curve, based on assumptions about the soil pore-size distribution and soil tortuosity. Most LSMs follow either Brooks and Corey’s or van Genuchten’s models, combined with Mualem’s model of soil pore distributions (cf. Marthews et al., 2014; Van Looy et al., 2017).	Brooks & Corey–Mualem van Genuchten–Mualem
<i>(2) Water flow in the lower soil profile</i>	
Often called <i>groundwater models</i> (see e.g. Batelis et al. (2020), although note in this chapter we define groundwater in terms of water table position rather than in relation to a fixed soil depth (see Glossary)).	CABLE MODFLOW LEAFHYDRO ParFlow
<i>(3) Runoff production models</i>	
The water balance equation (see text) allows us to calculate runoff (Beven, 2012) under certain assumptions about the distribution of water within gridcells. Some runoff production approaches involve assuming soil moisture storage capacities follow a constant probability distribution (e.g. PDM, CABLE) or can be derived from the local topography (TOPMODEL).	PDM CABLE TOPMODEL

Usually, the calculations of water balance and water table position in the soil profile are divided into three submodels, although in the framework of Earth System Models (ESMs) they may be integrated more closely.

In LSMs, it is still unusual for both the upper and lower soil profiles to be simulated in detail, e.g. most crop models still assume a soil profile with a ‘freely draining’ lower boundary, which generally implies that the lower soil profile model has been reduced to a single drainage flux just to maintain water balance requirements. A few LSMs that simulate only upper soil profiles have been coupled with groundwater models (see Batelis et al., 2020), and more are attempting to improve the representation of lower soil profile dynamics in their simulations. This is because doing so can greatly improve predictions of water table depths and therefore surface soil wetness and rates of evapotranspiration (Martinez-de la Torre and Miguez-Macho, 2019). An implicit difficulty in using two separate models to simulate the upper and lower soil profile is to ensure that the water table can move realistically all the way from the surface (under wet conditions) down to the level of the first aquifer (under dry conditions), and for the water table surface within the soil (i.e. the belowground phreatic surface) to be realistic at the local scale (e.g. no discontinuities) (cf. peatland simulators that solve these difficulties, e.g., Baird et al., 2012).

Soil biogeochemical cycling models (soil nutrient and carbon dynamics)

Nutrient dynamics in soil (biogeochemistry) are critical to determining soil and plant function (health) both in terms of nutrients (e.g. nutrient addition from litter and loss via leaching) and physical structure (e.g. compacting or cracking). Nutrients enter the soil via rainfall, leaf litter and debris inputs from surface vegetation, and the erosion of minerals within the soil matrix itself. After a certain delay, depending on the processes involved, nutrients then leave the soil by soil respiration (notably carbon in the form of CO₂ (carbon dioxide) and CH₄ (methane) and soil erosion (e.g. during dust storms, landslide events or as leachate, dissolved or entrained in surface or subsurface runoff). These fluxes are simulated by ‘soil biogeochemistry models’, which include soil carbon dynamics and soil degradation models (Table 2).

Depending on the balance of input and output of plant nutrients, organic material may accumulate in the soil (e.g. peatland formation) or decrease (soil degradation), with a wide range of implications and impacts for both human and natural ecosystems that depend on those soils. Decomposition in soil is mediated by soil fauna and microbes and is also strongly affected by soil hydraulics; the position of the water table will dictate whether decomposition within the soil is aerobic or anaerobic. The dynamics of decomposition is currently a very active area of research, including whether the activities of soil microbes need to be explicit in the model, or can be approximated by decay kinetics (Table 2). Many recent projects have also focused on the role of soil moisture in the control of soil C dynamics (e.g. the Norwegian MOCABORS project).

Soil carbon (C) is the largest terrestrial C pool (IPCC, 2021). Many climate change solutions rely on the capability of soil to accumulate carbon and store it long-term or actively help to increase this capability (e.g., the FAO’s RECSOIL initiative). Knowing the residence time of carbon within the soil, and being able to predict how this may change with warming, is critical to estimating the effectiveness of these solutions. However, there is a limit to how much carbon can be stored in soil (SOC saturation; e.g. Campbell and Paustian (2015) estimate up to 9% SOC in mineral soils under agricultural use), therefore land management solutions intended to increase SOC storage have their limits, which must also be estimated. Models of carbon, water, nitrogen and even phosphorus dynamics are key to providing these estimates.

Deep soil

The importance of biogeochemical processes at depth in soil has been highlighted by many research projects, with attention drawn to our lack of both theory (Campbell and Paustian, 2015) and observations (Marthews et al., 2014) for the lower part of the soil profile. There has long been an assumption in soil science that at a certain depth in the soil biotic activity decreases to become negligible and below that the material is simply rock at varying stages of weathering (i.e. a C horizon, Fig. 3). Although soil organic matter (SOM) is highly concentrated at the surface because it derives mainly from decomposing surface litter (e.g. for carbon

Table 2 Overview of soil biogeochemistry models.

Models are divided into those that simulate soil microbial decomposition via microbial and chemical kinetics (K) and those that attempt a more process-based representation of microbial dynamics (M) (cf., Chadburn et al., 2020).

accounting SOM it is assumed to be zero below 1-m depth (Rodeghiero et al., 2009), we cannot exclude the possibility of significant soil biogeochemical dynamics at depth. Soil sampling across the globe seldom extends below a few meters and information from microwave remote sensing is limited to the top few centimeters of the soil, therefore information on vertical distributions of SOM is currently quite limited.

Although tree roots below 10 m are rare in all biomes, microbial activity at depth can nevertheless be significant and does affect soil biogeochemical cycling (Richter and Markewitz, 1995; Campbell and Paustian, 2015; Lennon, 2020). Evidence is also accumulating that soil respiration measured at the soil surface does not represent total emission, as is commonly assumed (Rodeghiero et al., 2009), because an unknown quantity of CO₂ emitted from deeper soil layers is absorbed by water held in shallower soil layers before it reaches the surface (Richter and Markewitz, 1995; Gross and Harrison, 2019).

Tree roots may be rare below 10 m, but it does not mean that they are absent (Yang et al., 2016) and these taproots may be significant for vegetation persistence under drought. It should be expected that larger plant species will evolve root distributions that display a peak of coarse root density at the average annual water table depth (to absorb day-to-day water), a peak of fine root density close to the surface (to absorb nutrient input from surface litterfall) and a small number of taproots as deep as possible to be activated during drought or severe dry seasons. Global data on rooting depth are increasing (Yang et al., 2016), although it should be kept in mind that estimates of rooting depth aim to identify the level below which root activity becomes minimal. Therefore, they are arguably closer to an estimate of the depth of the base of the subsoil (B-C horizon boundary, Fig. 3) rather than a hard limit below which roots cannot occur (the activity of taproots may be episodic, e.g. in response to drought, and therefore challenging to capture from observations).

Soil heat balance and thermal dynamics models

The current ISMC Working Group on [Soil Thermal Properties](#) aims to evaluate the current use of empirical functions to estimate soil thermal properties (including heat conductivity and heat capacity). The flow of heat into and out of the soil determines soil temperature in each layer of the soil profile. Soil temperature is important because it influences the physical, chemical, and microbiological processes that take place in the soil and at the soil surface, including the types and rates of chemical reactions within the soil, and energy and mass exchange with the atmosphere (Hillel, 2004). Thermal conductivity is strongly influenced by hydrology, hence simulating soil moisture and groundwater (section “Soil moisture model components (hydraulics and hydrology)”) is an important prerequisite for modeling thermal dynamics (He et al., 2020). Models of soil thermal conductivity have a long history, but they are still under development (Table 3).

Recently, there has been progress in representing coupled heat and vapor flow at the soil surface, which is usually represented with relatively high uncertainty in LSMs (Lekshmi and Arnepalli, 2017). In addition, global warming will entail significant increases in soil temperatures and soil thermal dynamics. Currently, evidence is mixed on the dependence of land–atmosphere fluxes on soil temperature (e.g. soil respiration, Carey et al., 2016). Research is ongoing to identify these dependencies and linkages in order to estimate how much (or whether) rising soil temperatures will fuel significant increases in global temperatures (Carey et al., 2016).

Extreme environments

The standard approach to modeling of the soil environment outlined here (Fig. 1) should be considered a starting point only, and requires modification for more detailed work in particular biomes. Here, we focus on three example biomes where soil modeling encounters particular challenges. We consider these to be extreme environments in a global sense: for example, dryland forests cover only 7% of global land and would therefore be considered extreme by most of the global population, despite being the norm for the people for whom these areas are home.

Drylands and dry forests

There are many challenges to human life in global drylands that are caused by or aggravated by changes in the local soil environment. In these regions, soil erosion and loss can be overwhelming, and there is strong motivation for simulation models to be formulated that can address some of these challenges. In very dry soil, the liquid water content inside the soil matrix is no longer continuous so capillary forces become negligible and the strength of adsorptive forces controls water retention (i.e. soil moisture is dominantly hygroscopic). Standard soil hydraulic models arguably do not model these effects well, simply assuming

Table 3 Overview of soil thermal conductivity and thermal capacity models (refer to Rerak (2017)).

Model	Notes
Johansen model	Johansen (1977)
Johansen model with revised thermal conductivity	Chadburn et al. (2015) (recommended for organic soils)

that a certain amount θ_{res} of soil water is ‘residual’, in the sense of being unavailable to plants (Marthews et al., 2014). Improving the model representation of desorptive drying in very dry soil could greatly improve the reliability of LSMs when run for dryland environments.

Fire, soil compaction, desertification and large-scale erosion events are often considered infrequent events, but in drylands they are part of the normal seasonal cycle and therefore must be accounted for in simulations. Burning, for example, can greatly affect soil properties, depending on the extent, intensity and duration of the fire (Certini, 2005). Although heat in moist soil penetrates more deeply, the latent heat of vaporization prevents soil temperatures from exceeding 95 °C until water completely vaporizes. In completely dry soil, however, temperatures can typically rise to 200–700 °C depending on fuel availability. Below the surface, the temperature gradient is very steep: at 5 cm in the mineral soil temperatures rarely exceed 150 °C and often no heating occurs below 20–30 cm (Certini, 2005). The effects of fire on soil are numerous, however, including significant removal of organic matter, deterioration of both structure and porosity, loss of nutrients through volatilization, ash entrapment in smoke columns, leaching and erosion, and marked alteration of both quantity and specific composition of microbial and soil-dwelling invertebrate communities.

Tropical moist and wet forests

Moist and wet tropical forest environments present particular difficulties for soil models: their soils are usually not only macroaggregated, but also interlaced with a large root density and exist in areas of the globe where high precipitation over geological periods of time has produced unique soil types with different hydraulic and hydrological properties. In very wet soil, the soil is almost always saturated or close to saturation. Therefore, capillary forces become negligible compared to gravitational flow, and standard soil hydraulic models, which emphasize capillary effects, arguably do not model these effects well (Marthews et al., 2014).

Fire should also be mentioned in this context: although natural wildfires are generally restricted to drylands, prescribed burning can occur in any biome and is widely used in tropical forests as an aid to deforestation (e.g. the Amazonian Arc of Deforestation). In addition to the known effects on vegetation, fires greatly affect soil structure (see above) in ways that are not generally included in LSMs.

Cold regions

High latitude ecosystems have long been poorly represented in LSMs, broadly because of a lack of observational data (Chadburn et al., 2015). Boreal forests, tundra and other Arctic and Antarctic ecosystems have an important role in global budgets of CO₂ and CH₄ and influence much of the seasonal and annual climatology of the rest of the globe. The representation of cold soil processes within LSMs (e.g. snow, ice, frozen soil and permafrost dynamics) has recently come into sharp focus because the Arctic, in particular, is experiencing approximately twice the rate of warming as the rest of the globe (Arctic amplification, Richter-Menge et al., 2019).

In the boreal zone, the widespread thawing of permafrost is of great concern and may in the future lead to significant infrastructure damage in many regions. The [Global Terrestrial Network for Permafrost](#) (GTN-P) was developed in the 1990s to organize and manage a global network of permafrost observations for detecting, monitoring and predicting climate change. Many global models represent specific cold-region soil processes such as the phase change associated with freezing and thawing, and more recently have begun to include excess ice and thermokarst processes.

Peatlands and wetlands

Peatlands occur in all regions except the high polar regions: they represent some of the most productive ecosystems in the world and are of particular global focus today (e.g. the [International Peatland Congress 2021](#)). Peatlands, with their deep organic layers and large carbon content, tend to form in water-saturated soils where anoxic conditions suppress decomposition (Parish et al., 2008). Peat represents a globally-relevant and potentially unstable carbon stock, and often lies beneath some of the most biodiverse forest ecosystems on the planet. Progress has been made in representing peatland hydrological dynamics and carbon fluxes, but a reliable representation of the coupled interactions between carbon and hydrology that determines peatland stability and resilience has not yet been successfully formulated for large-scale LSMs (see discussion in Chadburn et al., 2020).

Wetland environments are characterized by seasonally or permanently inundated soils. In these areas, interaction of the flow regime and water table is crucial: if the flow regime is variable with frequent floods then fluvial input will be significant, but if the water table is very close to the surface then groundwater input will be significant. Wetlands are also key nodes in the global methane (CH₄) cycle; they are the largest natural source of methane that goes into the atmosphere (Chadburn et al., 2020). Methane emission is primarily a function of soil temperature and substrate C availability (Chadburn et al., 2020), but water flow is also important (with emission from flowing water often assumed to be negligible compared to that from stagnant water - cf. the division between depression storage and detention storage (see Glossary)).

Global peatlands demonstrate most clearly that soil is not just a passive substrate but a dynamic one that changes its volume and physical makeup over time, not only because of deposition or erosion of material by external processes (e.g. hydrological, eolian, including e.g. landslides) but also because of accumulation and loss through internal processes (Baird et al., 2012; Chadburn et al.,

2020). The need for LSMs to include a dynamic soil module that can simulate these processes is clear from the point of view of long-term peatland development.

New directions in land surface simulation

Hyperresolution

There are currently two leading edges of development in LSMs: First, the move to higher resolution (Beven et al., 2015), which is being driven predominantly by the movement in meteorology toward convection-permitting models that require sub-daily temporal resolution and spatial resolutions finer than 4–5 km (Kendon et al., 2021). At these spatial resolutions, many aspects of the land surface that were approximated as ‘subgrid’ processes previously must be given a more process-based treatment (Beven et al., 2015; Fisher and Koven, 2020).

Coupled model environments

A second leading edge is the move toward coupled model simulations, where there is two-way data exchange between simulation elements (e.g. land surface, ocean, atmosphere). Before the 2000s, climate models and LSMs were always separate models, but since then there has been a broad global effort to integrate simulated systems more closely and produce fully-coupled models of the whole global environment, i.e. Earth system models (ESMs) (Clark et al., 2015). The ESMs generally include a more integrated approach to the modeling of soil processes (Campbell and Paustian, 2015; Fisher and Koven, 2020). A great advantage of ESMs is that they allow the known influence of the soil on the atmosphere to be characterized much more reliably than either climate models or LSMs in isolation (e.g. the dynamics of the tropical rainbelt). Efforts to improve coupled modeling approaches are being coordinated through the WCRP’s Coupled Model Intercomparison Project Phase 6 (CMIP6), a worldwide modeling effort initiated in 2016 that is fostering improvements in climate models, LSMs and ESMs (IPCC, 2021).

Conclusions

Soil covers almost the entire land surface of the Earth: only at the highest reaches of mountain ranges or deep below permanent glaciers and ice sheets does the effect of soil on surface life become negligible. Soil influences or controls an enormous variety of aspects of the functioning of the land surface, ranging from the yield of crops in agricultural fields, to the dynamics of vegetation in natural ecosystems, to the velocity of floodwaters in river catchments. The shape of the soil surface around us defines many aspects of all of our lives.

Land Surface Models (LSMs) have been through several generations of development since they were first formulated in the 1960s, but have arguably not yet fulfilled their potential to solve key societal and scientific questions related to environmental resilience (Fisher and Koven, 2020). The representation of soil in LSMs and in elements of other climate models is undergoing rapid development, and the relevance and importance of soil to current efforts to understand and mitigate climate change is becoming increasingly recognized.

The United Nations Secretary General, António Guterres, said in his State of the Planet speech in December 2020: “Covid and climate have brought us to a threshold” and that “Making peace with nature is the defining task of the 21st century.” Although the effects of soil processes are only one part of climate change, they are a critically important part and it is therefore timely to identify the most important issues we face in each of the major global biomes.

A balance must be struck between model realism (which often requires complexity) and tractability (runtimes must not be impracticably long), the need for an improved representation of soil hydrological, biogeochemical and other processes is becoming clear. Looking ahead to the future, we anticipate a new generation of soil models with greater consideration in their make-up of the formation, development, organic and physical influences on the biosphere, and long-term accumulation, erosion and loss of soil profiles. We believe that to address the challenges of climate change, the multiple effects of soil processes will also need to be reflected in the context of all good climate and land surface models.

EDITORS BIOGRAPHY

Michael J Goss, PhD, MSc, BSc, is a professor emeritus in the School of Environmental Sciences at the University of Guelph. Before taking on the joint editor-in-chief responsibilities with Margaret Oliver, he held a similar position for *Soil Use and Management*, a journal of the British Society of Soil Science of which he is an honorary fellow. He was an inaugural member of the European Society for Agronomy. Michael started his career at the Letcombe Laboratory before moving to Rothamsted Experimental Station and the Macaulay Land Use Research Institute (now the James Hutton Research Institute). In 1990 he was appointed to the Research Chair in Land Stewardship at the University of Guelph and in 2005 became the director of its Regional Campus near Ottawa.

Michael's research has covered soil plant relations, soil management, and agriculture's footprint on the environment. His focus has been on the physical properties of soil and their impacts on root growth, which he showed to be influenced by the role of the root cap. He broadened his approach to include the effects of tillage and land drainage on root exploration. This work stimulated his interest in the transport of materials, such as plant nutrients, pathogenic microbes, antibiotics, and biologically active compounds through the soil and their contamination of water resources. Michael's knowledge in this field resulted in his involvement in the public inquiry into the death of seven people, including children, from a microbially contaminated drinking water supply. He contributed, both to the investigation into how the contamination occurred and if any fault could be attributed to local agricultural practices, and to how to prevent future events.

Michael also developed an interest in the interrelationships between soil microbes and root systems, particularly the tripartite symbiosis between roots of legumes, mycorrhizal fungi, and rhizobia. He has been an energetic member of collaborative research programs in France and Germany, and in Portugal, where he continues his interest in the role of mycorrhiza in sustainable land management.

Michael has authored more than 180 publications including two books, one in its 2nd edition, and edited two others.

Margaret Ann Oliver (BSc, PhD)

Margaret's interest in soil began in her penultimate year at school when learning about different types of soil and their formation. She chose the University of Bristol, United Kingdom for her first degree because the geography course offered soil science and she was also able to do a degree in geology alongside. Her love for both subjects remains undiminished. She did her PhD in soil spatial analysis at the University of Birmingham. Her early research focused on the multivariate and geostatistical analysis of soil data, which she continued to use in various research projects. Her research interests expanded to include the application of a wide range of numerical and geostatistical methods to soil and other data including pollen counts, forestry, radon emission, remotely sensed imagery, precision agriculture, and the incidence of childhood cancer. Her specific interests have been in sample design for spatial analysis and eventual mapping, risk analysis associated with prescribed thresholds in relation to soil pollutants or deficiencies of crop nutrients, and the relations between different scales of spatial variation. Her most

recent research was in the field of precision agriculture. At both the Universities of Birmingham and Reading, she taught topics in soil science, statistical methods, and spatial analysis. At Reading she had a research group working on various projects such as imagery, sampling and mapping, precision agriculture, and human health.

She has published more than 100 academic papers and has made several contributions to books. She is the co-author of three books: *Statistical Methods in Soil and Land Resource Survey*, Oxford University Press (Webster, R and Oliver, M. A. 1990); *Geostatistics for Environmental Scientists*, Second Edition, John Wiley & Sons (Webster, R and Oliver, M. A. 2007), and *How to do the Basic Steps in Geostatistics: The Variogram and Kriging*, Springer, Dordrecht (Oliver, M.A. & Webster, R.2015). She has edited two books: *Geostatistical Applications for Precision Agriculture* (Springer, Dordrecht, 2010) and *Precision Agriculture for Sustainability and Environmental Protection* (Earthscan from Routledge, 2013).

Margaret retired officially from Reading in 2004, but as yet has not managed to escape from academia. She has retained a link and a base at the University as a visiting professor since January 2005. After retirement, she developed and taught geostatistics courses to outside groups for several years. She then started on the long path of editorial work, as an associate editor of the *European Journal of Soil Science* and eventually the editor-in-chief, assistant editor of *Mathematical Geosciences*, co-editor of *Precision Agriculture* with John Stafford, and finally the editor-in-chief of the *Encyclopedia of Soils in the Environment* with Michael Goss.

Margaret was made an honorary member of the British Society of Soil Science in 2021 to reflect her commitment to soil science through fellow research, teaching, and editorial work. She was honored by the Pedometrics Commission of the International Union of Soil Science by having an award named after her in 2015. It is the Margaret Oliver award for young pedometricians.

EDITORIAL BOARD

Editors in Chief

Michael J Goss

FOREWORD

Soil is the porous “skin” on the surface of the Earth that has formed over thousands of years of weathering, comprising minerals, organisms (both dead and alive), water, and air. Soil is more than just the sum of its parts. It serves several crucial ecological functions, from food and fiber production to water storage and purification to waste decomposition.

Increasingly we understand that everything is connected, and that soil is a “Critical Zone” that intersects with the hydrosphere (water), lithosphere (minerals), atmosphere (air), and biosphere (all living organisms). To quote Daniel Hillel, the 2012 World Food Prize laureate and editor of the First Edition of *The Encyclopedia of Soils in the Environment*, “[Soil] is the crucible of terrestrial life, within which biological productivity is generated and sustained...Our civilization depends on the soil...” He also promoted the importance of understanding soil to manage it effectively. This revised and reorganized second edition of the Encyclopedia aims to reflect the changing status of soil in the world. Within these five volumes, over 724 experts from many countries have provided updated, easy-to-understand chapters on soil, its properties, and its role in the environment to affect climate change, plant productivity, human health, and biodiversity.

Many technological advances have been made since the first edition of this encyclopedia that has allowed us to investigate soil physical, chemical, and especially biological properties more precisely, enabling us to identify and understand their roles in ecosystem services. The study of soils, especially in the environmental context, is critical to meeting the challenges of feeding, clothing, and cleaning up the world. The information presented in these volumes will be useful to many, including soil and environmental scientists, policymakers, land managers, educators, students, and anyone interested in learning more about soil.

Soil is under considerable threat from many sources—building and infrastructure, climate change, population pressure, and pollution, yet it is vital to agronomic productivity and continues to provide critical ecosystem services. Society needs to be engaged in how soil is managed and conserved. Most natural scientists are very dedicated and generous, including all of the authors in this Encyclopedia who have freely given their time to make these volumes so comprehensive. The study of soil, while often challenging, is fascinating—soil is a beautiful earthy material that can delight our senses with its variegated colors, gritty to smooth textures, and especially its characteristic aroma when freshly turned. Perhaps that is why gardeners and even some farmers tend to overwork their soil to its detriment—it *just feels good to get your hands in the dirt!*

Soil science is one of the most exciting, interesting, and rewarding disciplines, largely because it is multi-dimensional and interdisciplinary, basic and applied. It affects all of our lives. Thus, I encourage you to peruse these volumes and discover all kinds of interesting aspects of soil in the environment.

April Ulery

Former President, Soil Science Society of America
Professor, Soil & Environmental Sciences
New Mexico State University
Las Cruces, NM
The United States

PREFACE

This second edition of the *Encyclopedia of Soils in the Environment* follows in the footsteps of a highly rated first edition overseen by Professor Daniel Hillel as editor in chief, ably assisted by six editors. That edition provided a very valuable resource on the “state-of-the-art” in soil science in the context of the environment in the closing years of the twentieth century and the first three years of the current century. It set a standard that the editorial team for the second edition has aimed to match. The soil and environmental sciences have made huge strides in the almost 20 years since the first edition was published, and the new team has had to embrace these developments while retaining the basic components of these sciences. The project has taken 4 years to complete. It began with the appointment of the two editors-in-chief, professors Michael J. Goss and Margaret A. Oliver, followed by that of the nine subject editors and a pedology adviser.

The project was in its infancy (a few months only) when COVID-19 struck. The editors-in-chief discussed the format and structure of the second edition around the time that the first “lockdowns” around the world were being introduced. The first edition was alphabetically organized, whereas we decided to have a section-oriented approach in this edition, which we hope gives a more structured feel for the various topics embraced. The principal sections are soil biology, soil chemistry, the soil environment and its management, pedology (the origins and development of soil), pedometrics (the application of mathematics and statistics to soil), and soil physics. We were able to give our full attention to this development and to the selection of the scientists to join us on the road ahead. Furthermore, we were fortunate to choose a team that has maintained its enthusiasm despite the many tribulations we have faced along this path. The team comprises Jane Blagodatskaya and Adrian Unc (biology and microbiology), Siobhan Staunton and Baoshan Xing (chemistry), Karin Müller and Christina Siebe (environment and management), Rupert Bäumler (pedology), Uta Stockmann and Margaret Oliver (pedometrics), and Paul Hallett and Dani Or (physics). The editorial board has been mindful in their choice of subjects of the need for basic soil science and for state-of-the-art developments, with the aim that the audience for these volumes can be as large as possible.

During the gestation period of the Encyclopedia, methods of working for those in academia were turned on their heads. The change from “face-to-face” teaching to formulating and establishing online courses, initially for lockdown periods but then for much of the next 2 years, had huge consequences for academic staff worldwide. This meant that they had less time to devote to outside activities, such as writing chapters for an encyclopedia. As a result, some authors were unable to complete their chapters in time, leaving a few unfortunate gaps. The whole team has done as much as they can to limit any adverse effects, but we ask readers to appreciate the struggle that authors have had with illness (personal, within their families and work colleagues) and a great increase in their workload. Despite this, we are presenting a comprehensive document that should stand the test of the next 20 years of soils in the environment.

This century has seen an almost unprecedented interest in the soil and environmental sciences. It has been triggered not only by issues that the Earth is facing from global climate change, increasing population pressure, soil and land degradation, and food insecurity but also by the many new and sophisticated methods available, such as the DNA determination of microbial populations and their functional capabilities, proximal sensing, machine learning methods, and an ever-increasing array of technological tools. These developments have greatly increased our knowledge and appreciation of the complexity of soils, which has changed our understanding of some well-established aspects of the science. The soil and its environment are at the critical interface of the atmosphere, biosphere, hydrosphere, and lithosphere. They deserve to be taken seriously by the international community in the same way that air and water have been. Governments are now paying attention

to the soil and environment, and a legal and governance framework is emerging to look after these parts of our life support resources.

We have aimed, through our editing of chapters, to make the language of the chapters accessible to all, regardless of educational background. This does not mean that we have diminished the scientific content, but that readers should be able to gain the foothold they desire in these subjects to progress to greater knowledge and understanding of them. We have retained the overview of soil written by Daniel Hillel for the First Edition, first to honor his great contribution to soil science and second to demonstrate the significance of soil. It follows this Preface.

*Michael J. Goss
Margaret A. Oliver*

SOIL

The term “soil” refers to the weathered and fragmented outer layer of our planet’s land surfaces. Formed initially through the physical disintegration and chemical alteration of rocks and minerals by physical and biogeochemical processes, soil is influenced by the activity and accumulated residues of a myriad of diverse forms of life. As it occurs in different geologic and climatic domains, soil is an exceedingly varied body with a wide range of attributes.

Considering the height of the atmosphere, the thickness of the earth’s rock mantle, and the depth of the ocean, one observes that soil is an amazingly thin body—typically not much more than one meter thick and often less than that. Yet it is the fount of terrestrial life, within which biological productivity is generated and sustained. It acts like a composite living entity, a home to a community of innumerable microscopic and macroscopic plants and animals. A mere fistful of soil typically contains billions of microorganisms, which perform vital interactive biochemical functions. Another intrinsic attribute of the soil is its sponge-like porosity and its enormous internal surface area. That same fistful of soil may actually consist of several hectares of active surface, upon which physicochemical processes take place continuously.

Realizing humanity’s utter dependence on the soil, ancient peoples, who lived in greater closeness to nature than many of us today, actually revered the soil. It was not only their source of livelihood but also the material from which they built their homes and that they learned to shape, heat, and fuse into household vessels and writing tablets (ceramics, made of clayey soil, being the first synthetic material in the history of technology). In the Bible, the name assigned to the first human was Adam, derived from “adama,” meaning soil. The name given to the first earthling’s mate was Hava (Eve, in transliteration), meaning “living” or “life-giving.” Together, therefore, Adam and Eve signified quite literally “Soil and Life.”

The same powerful metaphor is echoed in the Latin name for human species—Homo, derived from humus, the material of the soil. Hence, the adjective “human” also implies “of the soil.” Other ancient cultures evoked equally powerful associations. To the Greeks, the earth was a manifestation of Gaea, the maternal goddess who, impregnated by Uranus (god of the sky), gave birth to all the gods of the Greek pantheon.

Our civilization depends on the soil more crucially than ever because our numbers have grown while available soil resources have diminished and deteriorated. Paradoxically, however, even as our dependence on the soil has increased, most of us have become physically and emotionally detached from it. Many of the people in the so-called developed countries spend their lives in the artificial environment of a city, insulated from direct exposure to nature, and some children may now assume as a matter of course that food originates in supermarkets.

Detachment has bred ignorance, and out of ignorance has come the delusion that our civilization has risen above nature and has set itself free of its constraints. Agriculture and food security, erosion and salination, degradation of natural ecosystems, depletion and pollution of surface waters and aquifers, and decimation of biodiversity—all these processes, which involve the soil directly or indirectly, have become abstractions to many people. The very language we use betrays disdain for that common material underfoot, often referred to as “dirt.” Some fastidious parents prohibit their children from playing in the mud and hurry to wash their “soiled” hands when the children nonetheless obey an innate instinct to do so. Thus, soil is devalued and treated as unclean though it is the terrestrial realm’s principal medium of purification, wherein wastes are decomposed and nature’s productivity is continually rejuvenated.

Scientists who observe soil closely see it in effect as a seething foundry in which matter and energy are in constant flux. Radiant energy from the sun streams onto the field and cascades through the soil and the plants growing in it. Heat is exchanged, water percolates through the soil’s intricate passages, and plant roots extract

water and transmit it to their leaves, which transpire it back to the atmosphere. Leaves absorb carbon dioxide from the air and synthesize it with soil-derived water to form the primary compounds of life. Oxygen emitted by the leaves makes the air breathable for animals, which consume and in turn fertilize plants.

Soil is thus a self-regulating bio-physio-chemical factory, processing its own materials, water, and solar energy. It also determines the fate of rainfall and snowfall reaching the ground surface—whether the water thus received will flow over the land as runoff, or seep downward to the subterranean reservoir called groundwater, which in turn maintains the steady flow of springs and streams. With its finite capacity to absorb and store moisture, and to release it gradually, the soil regulates all these phenomena. Without the soil as a buffer, rain falling over the continents would run off entirely, producing violent floods rather than sustained river flow.

Soil naturally acts as a living filter, in which pathogens and toxins that might otherwise accumulate to foul the terrestrial environment are rendered harmless. Since time immemorial, humans and other animals have been dying of all manner of diseases and have then been buried in the soil, yet no major human disease is transmitted by it. The term antibiotic was coined by soil microbiologists who, as a consequence of their studies of soil bacteria, specifically actinomycetes, discovered streptomycin (an important cure for tuberculosis and other infections). Ion exchange, a useful process of water purification, also was discovered by soil scientists studying the passage of solutes through beds of clay.

However unique in form and function, soil is not an isolated body. It is, rather, a central link in the larger chain of interconnected domains and processes comprising the terrestrial environment. The soil interacts both with the overlying atmosphere and the underlying strata, as well as with surface and underground bodies of water. Especially important is the interrelation between the soil and climate. In addition to its function of regulating the cycle of water, it also regulates energy exchange and surface temperature.

When land is cleared of vegetation and turned into a cultivated field, the native biomass above the ground is often burned and the organic matter within the soil tends to decompose. These processes release carbon dioxide into the atmosphere, thus contributing to the Earth's greenhouse effect and to global warming. On the other hand, the opposite act of afforestation and soil enrichment with organic matter, such as can be achieved through conservation management, may serve to absorb carbon dioxide from the atmosphere. To an extent, the soil's capacity to store carbon thus helps to mitigate the greenhouse effect.

Thousands of years are required for nature to create life-giving soil out of sterile bedrock. In only a few decades, however, unknowing or uncaring humans can destroy that wondrous work of nature. In various circumstances, mismanaged soils may be subject to erosion (the sediments of which tend to clog streambeds, estuaries, lakes, and coastal waters), to leaching of nutrients with attendant loss of fertility and eutrophication of water bodies, to waterlogging and impaired aeration, or to an excessive accumulation of salts that may cause a once-productive soil to become entirely sterile. Such processes of soil degradation, sometimes called "desertification," already affect large areas of land.

We cannot manage effectively and sustainably that which we do not know and thoroughly understand. That is why the tasks of developing and disseminating sound knowledge of the soil and its complex processes have assumed growing urgency and importance. The global environmental crisis has created a compelling need for a concentrated, concise, and definitive source of information—accessible to students, scientists, practitioners, and the general public—about the soil in all its manifestations in nature and in relation to the life of humans.

CONTENTS OF ALL VOLUMES

VOLUME 1: SOIL BIOLOGY

Overview

Edaphology	1
<i>RM Goss and AL Ulery</i>	

Biodiversity	10
<i>Monica A Farfan and Diana H Wall</i>	

Soil organisms

Bacteriophage (Viruses)	16
<i>Li Bi, Ji-Zheng He, Dan-Ting Yu, Li-Li Han, and Hang-Wei Hu</i>	

Archaea	25
<i>Mikhail V Semenov</i>	

Bacteria	31
<i>Mikhail V Semenov</i>	

Soil protists	39
<i>Stefan Geisen, Nathalie Amacker, and Alexandre Jousset</i>	

Fungi including mycorrhizal fungi	49
<i>F Buscot</i>	

Soil algae	61
<i>Karen Baumann and Patrick Jung</i>	

Soil arthropods: Underfoot and all around	70
<i>Ernest C Bernard</i>	

Nematodes	105
<i>Deborah A Neher and Thomas O Powers</i>	

Earthworms: Essential ecosystem engineers providing vital ecosystem services	112
<i>Maria JI Briones</i>	

Complex structures

Soil biofilms: Evolving concepts and ecological functions	120
<i>Yichao Wu, Marc Redmile-Gordon, Peng Cai, Chunhui Gao, and Qiaoyun Huang</i>	

Biocrusts	127
<i>Matthew A Bowker, Jasmine Anenberg, Hilina Yohannes Kebede, Anita Antoninka, and Lydia Bailey</i>	

Functioning

Studying soil microbial communities: Culture-dependent approaches	139
<i>Eduardo K Mitter, Dasiel Obregon, Micaela Tosi, Heather Slinn, and Kari Dunfield</i>	

Studying soil microbial communities: Culture-independent approaches	146
<i>Tolulope Mafa-Attoye, Heather Slinn, Micaela Tosi, Evan Mayer, Dasiel Obregon, and Kari Dunfield</i>	

Studying microbial function in soil: Culture-independent techniques <i>Micaela Tosi, Dasiel Obregon, Heather Slinn, and Kari Dunfield</i>	155
Kinetics of microbial processes: General principles <i>NS Panikov</i>	168
Kinetics of microbial processes: Applications to soil biology <i>NS Panikov</i>	186
Biogeochemical cycles	
Carbon cycle in soils: Dynamics and management <i>Charles W Rice, Carlos B Pires, and Marcos VM Sarto</i>	219
Carbon storage in soils <i>Isabelle Basile-Doelsch, Tiphaine Chevallier, Marie-France Dignac, and Amandine Erktan</i>	228
Soil organic nitrogen <i>EJ Daly and KA Congreves</i>	243
Nitrification: Process, organisms and management <i>Jeanette M Norton and Yang Ouyang</i>	253
Microbial denitrification <i>Michael J Goss, Sergey Blagodatsky, and Adrian Unc</i>	261
Symbiotic nitrogen fixation <i>Florence Mus and Hsin-Hua Wu</i>	270
Nitrogen: Non-Symbiotic Nitrogen fixation in soils <i>Vadakattu VSR Gupta and Sarah S Roley</i>	283
Phosphorus in soils—Biological interactions <i>Nataliya Bilyera and Iryna Loginova</i>	293
Biological transformations of sulfur in soil <i>Chaoqun Wang and Maxim Dorodnikov</i>	303
Plant uptake of mineral nutrients <i>Angela Hodge</i>	310
Higher plants and their interactions with soil organisms	
Soil Biology: Root form and function <i>Magda Garbowski, Grégoire Freschet, Louise Jackson, Cynthia Brown, and Louise Comas</i>	321
Root mucilage: Chemistry and functions in soil <i>Yutong Jiang, Lijun Hou, Fang Ding, and Joann K Whalen</i>	332
Root exudates and microorganisms <i>Aidan De Sena, Krisztina Mosdossy, Joann K Whalen, and Chandra A Madramootoo</i>	343
Root interactions with the microbiome from the rhizoplane to the bulk soil: An overview <i>Joann K Whalen and Shamim Gul</i>	357
Microorganisms & biological processes	
Soil respiration <i>Jeremiah D Vallotton, Sergey Blagodatsky, and Adrian Unc</i>	369
Anaerobic soil processes <i>PW Inglett, D Said-Pullicino, and K Ramesh Reddy</i>	379
Mineral-organic-microbial interactions <i>Balwant Singh, Sabina Yeasmin, and Donald L Sparks</i>	387

Microbial ecology & management

Habitat for soil organisms and their functions <i>Alexandra Kravchenko and Andrey Guber</i>	407
Plant growth promoters <i>Elisa Gamalero, Gustavo Santoyo, and Bernard R Glick</i>	418
Inoculation with microorganisms <i>Maureen O'Callaghan and David Wright</i>	428
Biocontrol of soil-borne plant diseases <i>Mehrdad Mohammadiani and Matthew Bakker</i>	439
Management of soil biology for crop protection from biotic and abiotic stresses <i>Michael J Goss, Isabel Brito, and Mário Carvalho</i>	447
Trees, hedges, agroforestry and microbial diversity <i>Josiah B Judson, Joseph Holden, Pippa Chapman, and Marcelo Valadares Galdos</i>	469
Urban soil microbiome: Activity, diversity and functioning <i>Maria Korneykova, Ekaterina Kozlova, Kristina Ivashchenko, Maria Vasileva, and Viacheslav Vasenev</i>	480
Microbiology of extreme soil environments <i>Patrice Dion</i>	494
Microbial mobility and transport in soils <i>Mohammad Reza Mosaddeghi, Adrian Unc, Ali Akbar Mahboubi, and Azadeh Safadoust</i>	512

Biology of soil amendments & contaminant degradation

Biology of compost <i>Heribert Insam, Thomas Klammersteiner, and María Gómez-Brandón</i>	522
Landfarming and its microbiology <i>Naga Raju Maddela, Balasubramanian Ramakrishnan, Kadiyala Venkateswarlu, and Mallavarapu Megharaj</i>	533
Biodegradation of organic contaminants <i>PB Hatzinger and JW Kelsey</i>	547
Biological aspects of manure management <i>Natasha Rayne and Bee Khim Chim</i>	558
Septic systems and municipal waste disposal on land <i>Charles P Gerba, Michael J Goss, and Adrian Unc</i>	567

Climate change

Climate change impacts on soil biology <i>Alberto Canarini, Lucia Fuchslueger, François-Xavier Joly, and Andreas Richter</i>	578
---	-----

VOLUME 2: CHEMISTRY**Basic Soil Chemistry**

Acidity and acidification <i>Siobhan Staunton</i>	1
pH <i>Siobhan Staunton</i>	8
Buffering capacity <i>Siobhan Staunton and Ravi Naidu</i>	15
Soil specific surface area <i>Emmanuel Arthur, Markus Tuller, and Kurt D Pennell</i>	22

Soil Analytical Chemistry

Cation exchange capacity and reactions <i>Donald S Ross and Ulf Skyllberg</i>	32
Testing for nutrients in the soil and the environment <i>Antonio P Mallarino</i>	43
Metal extraction and analysis <i>Guo Wang and Honghong Li</i>	50
Soil organic matter: Composition <i>Markus Kleber</i>	58
Physical fractionation techniques <i>Sam J Leuthold, Michelle L Haddix, Jocelyn Lavallee, and M Francesca Cotrufo</i>	68
The use of stable isotopes in soil science: Low atomic number elements <i>Chiara Pistocchi, Isabelle Bertrand, Kristýna Kantnerová, Astrid Oberson, Federica Tamburini, and Roland A Werner</i>	81
The use of radioactive isotopes to study soil pools and processes <i>Timothy I McLaren</i>	96
The use of stable isotopes in soil science: Metals <i>Cécile Quantin and Damien Guinoiseau</i>	107

Periodic Table

Alkali metals in soils <i>Guy J Levy and Asher Bar-Tal</i>	116
Alkaline earth metals in soil <i>Justin B Richardson</i>	126
Transition metals in soil <i>Siobhan Staunton</i>	135
Nitrogen and ammonia in soils <i>Nicholas T Girkin and Hannah V Cooper</i>	142
Phosphorus in soil <i>Luisella Celi, Maria Martin, and Elisabetta Barberis</i>	152
Aluminum in soils <i>Syuntaro Hiradate</i>	167
Iron in soils <i>Trolard Fabienne and Guilhem Bourrié</i>	176
Sulfur and selenium in soil <i>Dongli Liang, Fei Zhou, and Mingxing Qi</i>	192
Arsenic in soil <i>Md Imran Ullah Sarkar, Afsana Jahan, Md Tofail Hossain, Mohammad Mahmudur Rahman, and Ravi Naidu</i>	201
Non-transition elements: Metals and metalloids in soils <i>Natasha, Sana Khalid, Muhammad Shahid, Faiz Rabbani, and Camille Dumat</i>	214
Lanthanides, actinides and radon <i>Franco Ajmone Marsan and Mery Malandrino</i>	225
Halogens in soils <i>Svensson Teresia, Thiry Yves, Bueno Maïté, and Oelmann Yvonne</i>	234
Transformation of metals and metalloids by microorganisms <i>Susan M Glasauer, Euan P Burford, and Geoffrey Michael Gadd</i>	243
Dynamics of radionuclides <i>Siobhan Staunton</i>	256
Silicon and other non-metal elements from Group 14 <i>Bruno Delvaux and Zimin Li</i>	263

Soil Physical Chemistry

Chemical equilibria	274
<i>Arthur Paul Schwab</i>	
Dissolution and precipitation processes	284
<i>Zhenqing Shi, Shiwen Hu, Rong Li, and Yang Lu</i>	
Reactions, redox potential and kinetics	297
<i>Trolard Fabienne and Guilhem Bourrié</i>	
Sorption of organic chemicals in soil	315
<i>Joseph J Pignatello</i>	
Sorption—Oxyanions	327
<i>CP Schulthess, H Wijnja, W Yang, Anahita Khosravi, and Baoshan Xing</i>	
Sorption—Metals	336
<i>Daniel G Strawn and Donald L Sparks</i>	
Sorption–desorption kinetics	343
<i>Gautier Landrot and Donald L Sparks</i>	
Sorption-desorption hysteresis	355
<i>Wenhao Wu, Hongxia Zhu, and Kun Yang</i>	
Surface charge and zero-charge points	368
<i>J Chorover</i>	
Flocculation and dispersion	376
<i>Guy J Levy and Isaac Shainberg</i>	

Soil Carbon Chemistry

Soil organic matter dynamics	387
<i>Yu Luo and Jianming Xu</i>	
Soil proteins	396
<i>Siobhan Staunton</i>	
Biochar: Properties, mechanisms, and interactions in the soil	406
<i>Balwant Singh, Shamim Mia, and Marta Camps-Arbestain</i>	
Dissolved organic carbon	421
<i>Jason James and Rob Harrison</i>	
Black carbon, pyrogenic carbon	432
<i>Heike Knicker</i>	
Fire effects on soil	448
<i>Stefan H Doerr, Cristina Santín, and Jorge Mataix-Solera</i>	
Interfacial reactions of microorganisms with minerals and organic matter	458
<i>Rota Wagai, Puu-Tai Yang, and Klaus Kaiser</i>	
Pesticide fate in soils	470
<i>Pierre Benoit, Laure Mamy, Carole Bedos, and Enrique Barriuso</i>	
Soil organic matter in molecular simulations	483
<i>Martin H Gerzabek, Daniel Tunega, Edgar Galicia-Andrés, and Chris Oostenbrink</i>	

Soil Physical Analysis

Raman spectroscopy	497
<i>Anupam Das and Huiyuan Guo</i>	
Fourier transform infrared spectroscopic methods of soil analysis	510
<i>Derek Peak</i>	
Electron paramagnetic resonance spectroscopy: Part I Historic Perspectives	519
<i>Giorgio S Senesi and Nicola Senesi</i>	

Electron paramagnetic resonance spectroscopy: Part II the view forward <i>Robert L Cook, Emmanuel Ampiah, Phillip T Sprunger, and Randall W Hall</i>	533
Fluorescence Spectroscopy: Part I Principles <i>Yong Zhang, Shuai Guo, and Chaoxian Wei</i>	544
Fluorescence spectroscopy: Part II practical applications <i>Yong Zhang, Chaoxian Wei, and Shuai Guo</i>	552
Near and mid infrared soil spectroscopy <i>Wartini Ng, Brendan Malone, Budiman Minasny, and Sangho Jeon</i>	567
Electron microscopic methods (TEM, SEM and energy dispersal spectroscopy) <i>Jian Zhao and Xia Liu</i>	575
Application of atomic force microscopy (AFM) on environmental interfaces <i>Saikat Ghosh, Zhang Di, Bo Pan, and Baoshan Xing</i>	589
Applications of nuclear magnetic resonance for the study of soils <i>Daniel H Lysak, Myrna J Simpson, and Andre J Simpson</i>	605
Neutron-gamma analysis of soil elements <i>Aleksandr Kavetskiy, Galina Yakubova, Nikolay Sargsyan, Stephen A Prior, and H Allen Torbert</i>	625
X-Ray Diffraction <i>Chao Wang and Cheng Gu</i>	642
Soil analysis using laser-induced breakdown spectroscopy <i>Débora Marcondes Bastos Pereira Milori, Ladislau Martin-Neto, Hero T Gollany, Diego Victor de Babos, Luis Carlos Leva Borduchi, and Paulino Ribeiro Villas-Boas</i>	654
Calorimetric analysis <i>Xingmin Rong and Qiaoyun Huang</i>	662
Understanding of soil processes at the microscale—Use of NanoSIMS in soil science <i>Carsten W Mueller, Carmen Hoeschen, and Ingrid Koegel-Knabner</i>	670
Nanoparticles in soil <i>Di Lang, Quan Chen, Yang Liu, and Bo Pan</i>	681
Overview	
Soil chemistry and climate change <i>Jianming Xu, Yong Li, and Zhongmin Dai</i>	692
VOLUME 3: ENVIRONMENT AND MANAGEMENT	
Soil functions, potential uses of soil and ecosystem services	
Soil functions, soil potential uses and ecosystem services <i>Karl Stahr</i>	1
Farming systems to conserve land for nature <i>Rattan Lal</i>	12
Geoarchaeology and soils <i>Carlos E Cordova</i>	20
Civilizations and the role of soil, agriculture, and climate change <i>Jeffrey A Homburg, Eric C Brevik, and Jonathan A Sandor</i>	29
Ecosystem services provided by soils in highly anthropized areas (SUITMAs) <i>Jean Louis Morel, Geoffroy Séré, Viatcheslav Vasenev, and Thomas Nehls</i>	37
Structure and function of forested soils <i>Peter Clinton and Jen Owens</i>	56
Agroforestry <i>NV Thevathasan, AM Gordon, and PKR Nair</i>	68

Rangeland management <i>Alexandra Sandhage-Hofmann</i>	88
Effects on soil of grassland management for pasture, hay and silage <i>Carmen Segura, Laura Cardenas, Richard McDowell, Sarah Morgan, and Martin SA Blackwell</i>	102
Dryland farming: Technological and management options for sustainable agriculture and food systems <i>Ch Srinivasarao, G Ranjith Kumar, Ravula Manasa, Kiran Pilli, Samaresh Sahoo, S Rakesh, Sumanta Kundu, K C Nataraj, KV Rao, JVNS Prasad, and S Malleswari</i>	113
The effect of crop rotations on soil <i>Caio Fernandes Zani, Arlete Simões Barneze, Rogério Peres Soratto, and Charles Andrew Francis</i>	125
The contribution of organic farming systems to soil fertility—A systems perspective <i>Bernhard Freyer, Pierre Ellssel, Jürgen K Friedel, and Kurt Möller</i>	135
Soil functions to support natural plant communities and crops: Soil multifunctionality <i>Leidivan Almeida Frazão, Luiz Arnaldo Fernandes, Adriana Marcela Silva Olaya, and Igor Costa de Freitas</i>	146
Methane and nitrous oxide emissions from land <i>Joanna M Cloy and Keith A Smith</i>	153
Soil and land degradation	
Overview chapter on soil degradation <i>K Müller, Margaret A Oliver, and C Siebe</i>	165
Soil monitoring <i>Ben Marchant and Nicolas Saby</i>	172
Soil quality and health key indicators <i>Edoardo AC Costantini and Simone Priori</i>	181
Water induced soil erosion <i>R Jane Rickson</i>	193
Erosion by wind <i>John Tatarko</i>	208
Human exposure to aeroparticles emitted from unpaved roads due to traffic resuspension and wind erosion <i>Arón Jazcilevich and Ann G Wellens</i>	223
Soil salination processes and management <i>Uri Nachshon and Guy J Levy</i>	236
Degradation of soil structure and soil organic matter <i>Andrew S Gregory</i>	246
Drainage, soil water storage, buffering and filtering <i>Jeffrey Strock and Norm Fausey</i>	257
Environmental effects of irrigation <i>Sevilay Topcu</i>	266
Trade-offs of wastewater irrigation <i>Manzoor Qadir and Christopher A Scott</i>	277
Pollution and risks of trace elements in the soil environment <i>Peng Wang, Fang-Jie Zhao, and Steve P McGrath</i>	288
Pollutants—Persistent organic <i>Rai S Kookana and Divina A Navarro</i>	296
Pollution by microplastic in agricultural areas <i>Nicolas Beriot and Esperanza Huerta-Lwanga</i>	309

Municipal solid waste management: Production, management, and environmental effects <i>Bryant M Serre and Lynda H McCarthy</i>	321
Remediation of metals and organic contaminants in soil <i>Peter Sanderson, Md Mezbaul Bahar, Bhabananda Biswas, and Ravi Naidu</i>	333
Soil change under different scenarios	
Soil change under different scenarios <i>Joann K Whalen</i>	344
The effect of global change on the soil body <i>Sophie Cornu, David Montagne, and Antra Boca</i>	360
The effects of adequate and excessive application of mineral fertilizers on the soil <i>Bijay-Singh and Tek B Sapkota</i>	369
Foliar Application of Nutrients <i>Thomas Eichert and Victoria Fernández</i>	382
Mulches and cover crops part I: Types <i>KK Bandyopadhyay, CL Acharya, and KM Hati</i>	392
Mulches and cover crops part II: Role in soil health and climate resilient agriculture <i>KK Bandyopadhyay, CL Acharya, and KM Hati</i>	401
The potential agronomic and environmental applications of biochar: Prospects and challenges <i>Yu-Jun Wang, Ping Wu, Nanthi S Bolan, and Hai-Long Wang</i>	414
Soil management for carbon sequestration <i>Christopher Brock, Uwe Franko, and Martin Wiesmeier</i>	424
Soil tillage <i>Mathieu Lamandé, Lars Juhl Munkholm, and Trond Børresen</i>	433
Weed and soil management: A balancing act <i>Trevor Kenneth James and Charles Norman Merfield</i>	439
Terraces as traditional agricultural landscapes. Stability amidst change <i>Gerardo Bocco</i>	450
Soil quality protection policies and plans to ensure sustainability <i>Ram Swaroop Meena and Sandeep Kumar</i>	457
Construction of Technosols for green roofs and vertical green system <i>Eleonora Flores-Ramírez, Stefan Abel, Elizabeth Chávez-García, and Geoffroy Séré</i>	473
Management of park areas, sport fields, and school yards, including golf courses and public right of ways <i>Maxine J Levin and Anna Paltseva</i>	488
Soil-society relations	
Overview chapter on soil-society relations <i>C Siebe, Margaret A Oliver, and K Müller</i>	505
Soil art: Sensory and symbolic engagement with soils <i>Alexandra R Toland and Daniel Wolter</i>	509
Soil science in the criminal justice system <i>Lorna Anne Dawson</i>	521
Soil governance at the international, regional and national level <i>Harald Ginzky</i>	532
The economics of soils' contribution to human well-being <i>Bartosz Bartkowski and Julian R Massenber</i>	547

Soil and human health	555
<i>Margaret A Oliver and Eric C Brevik</i>	
Soil Science Education, Awareness and Outreach in the Modern World	572
<i>Laura Bertha Reyes-Sánchez and Eric C Brevik</i>	
Soils in landscape planning	580
<i>Seth Denizen</i>	

VOLUME 4: PEDOLOGY

Pedology

Pedology—Basic principles	1
<i>Rupert Bäumler, Uta Stockmann, and Margaret A Oliver</i>	

Factors of soil formation, pedogenic processes and mineralogy

Overview chapter on factors of soil formation	7
<i>Rupert Bäumler, Margaret A Oliver, and Uta Stockmann</i>	
Factors of soil formation: Climate	14
<i>Stefaan Dondeyne, Stephan Mantel, and Seppe Deckers</i>	
Factors of soil formation: Soil biota and organic matter as a factor for soil formation and weathering processes	25
<i>Scott Werts</i>	
Soil forming factors: Parent material	34
<i>Stephen Nortcliff</i>	
Parent materials: Loess	42
<i>Tobias Sprafke</i>	
Time	48
<i>Susan E Melzer, Caroline M Yonker, and Eugene F Kelly</i>	
Factors of soil formation—Human impacts	54
<i>Jonathan A Sandor, C Lee Burras, Michael Thompson, and Skye A Wills</i>	
Dynamic soils	69
<i>Markus Egli and Dennis Dahms</i>	
Interactions between soils and climate change	82
<i>Cornelia Rumpel</i>	
Primary minerals	91
<i>Balwant Singh</i>	
Mineral components of the soil clay fraction	109
<i>Darrell G Schulze</i>	
Short-range ordered aluminosilicates	121
<i>Tetsuhiro Watanabe, James B Harsh, and Rota Wagai</i>	
Metal oxides	135
<i>Andreas C Scheinost and Balwant Singh</i>	
Soil morphology	149
<i>Phillip R Owens and Zamir Libohova</i>	
Soil micromorphology	171
<i>Rosa M Poch and Georges Stoops</i>	
Soil Classification and distribution	
History and principles of soil classification	185
<i>Maria Gerasimova and Dmitry Konyushkov</i>	

Soil classification systems: World reference base and soil taxonomy	197
<i>David Badía-Villas</i>	
World reference base for soil resources (WRB)	206
<i>Stephan Mantel, Stefaan Dondeyne, and Seppe Deckers</i>	
World soil map based on soil taxonomy	218
<i>Eswaran Padmanabhan and Paul F Reich</i>	
Soils as archives of city history	232
<i>Hermine Huot and Jean Louis Morel</i>	
Classification of soils by ecozones	
Ecozones and soils – An introduction	246
<i>Rupert Bäumler</i>	
Cold Region Soils: Part I—Distribution, Properties and Processes	250
<i>Nicolas A Jelinski, Chien-Lu Ping, and John CF Tedrow</i>	
Cold region soils: Part II – Genesis and classification	263
<i>Nicolas A Jelinski, Chien-Lu Ping, and John CF Tedrow</i>	
Boreal forest soils	280
<i>Gabriele Broll</i>	
Soils of humid cool temperate regions	289
<i>Nicolas A Jelinski, Justin B Richardson, and Edward A Nater</i>	
Grassland soils in the cool–arid–temperate ecozone (Steppe, grassland)	299
<i>Mengyang You, Xiaobing Liu, Rupert Bäumler, and Margaret A Oliver</i>	
Soils from a warm-temperate semi-tropical ecozone (Mediterranean) with humid winter months	319
<i>J Torrent, Marco Pfeiffer, and Juan José Ibañez</i>	
Arid and semi-arid subtropical and tropical ecozone (II)	332
<i>Bernhard Lucke</i>	
Humid subtropical ecozone with emphasis on Acrisols and Alisols	343
<i>Nilton Curi, Sérgio Henrique Godinho Silva, and Alberto Vasconcellos Inda</i>	
Soils of the humid and sub-humid tropics	353
<i>Karl Stahr and Ludger Herrmann</i>	
Classification of soils by properties and environmental settings	
Sodic soils	368
<i>Guy J Levy and Uri Nachshon</i>	
Organic soils	383
<i>Heike Schimmel and Wulf Amelung</i>	
The pedology of anaerobic soils	398
<i>John Hollis and Allan Lilly</i>	
Alluvium and alluvial soils	417
<i>Janis L Boettinger</i>	
Hydric Soils	424
<i>MJ Vepraskas and JF Berkowitz</i>	
Wetland soils	436
<i>Cornelius Wilhelm van Huyssteen</i>	
Paddy soils: Characteristics, productivity and management	447
<i>Stephan M Haefele</i>	
Volcanic soils and non-volcanic andic soils	458
<i>Rupert Bäumler and G Uehara</i>	

PEDOMETRICS**Pedometrics**

Overview of Pedometrics	471
<i>Alexandre MJ-C Wadoux, Inakwu OA Odeh, and Alex B McBratney</i>	

Statistics and soil data analysis

Statistics in soil science	486
<i>Richard Webster</i>	

Multivariate analysis for soil science	499
<i>Si Yang Han, Patrick Filippi, Mercedes Román Dobarco, Januar Harianto, Mathew S Crowther, and Thomas FA Bishop</i>	

Machine learning and processing of large data	509
<i>Madlene Nussbaum</i>	

The issue of scale and change of support in the spatial analysis of environmental data	521
<i>A Castrignanò, A Belmonte, and N Romano</i>	

Soil measurements in space and time

Sampling for soil survey	535
<i>DJ Brus</i>	

Handling of soil samples in the field, in transport to the laboratory and in the laboratory	551
<i>Claudy Jolivet, Céline Ratié, Déborah Chavrit, Nicolas Soler-Dominguez, and Antonio Bispo</i>	

Digital Soil Morphometrics	568
<i>Yakun Zhang, Alfred E Hartemink, Jingyi Huang, and Budiman Minasny</i>	

Proximal soil sensing in the field	579
<i>Mikaela Tilse, Uta Stockmann, and Patrick Filippi</i>	

Proximal sensing of soil moisture	591
<i>Markus Tuller, Ebrahim Babaeian, and Scott B Jones</i>	

Proximal sensing of land surface temperature	600
<i>Ebrahim Babaeian and Markus Tuller</i>	

Proximal sensing of evapotranspiration	610
<i>Ebrahim Babaeian and Markus Tuller</i>	

Remote sensing of soil moisture	618
<i>Alexander Gruber and Jian Peng</i>	

Remote Sensing of Soil Organic Carbon	631
<i>Bas van Wesemael and Sabine Chabrilat</i>	

Pedotransfer functions and their application to soil water dynamics	642
<i>Marcel G Schaap, Yonggen Zhang, and Attila Nemes</i>	

Spatial and temporal soil variation

Geostatistics: Modelling spatial variation	655
<i>Richard Webster</i>	

Uncertainty assessment of spatial soil information	671
<i>Gerard BM Heuvelink and Richard Webster</i>	

Digital soil mapping: Evolution, current state and future directions of the science	684
<i>Brendan Malone, Dominique Arrouays, Laura Poggio, Budiman Minasny, and Alex B McBratney</i>	

Geographical information systems (GIS) and soils	696
<i>S Grunwald and J Böhner</i>	

Precision agriculture	710
<i>James A Taylor</i>	

Foundations, measurements and trends in pedodiversity <i>Juan José Ibañez and Marco Pfeiffer</i>	726
Soil landscape modelling	
Modeling soil development in a landscape context <i>Peter A Finke, Budiman Minasny, and Arnaud JAM Temme</i>	739
Climate and land surface models: Role of soil <i>Toby Richard Marthews, Holger Lange, Alberto Martínez-de la Torre, Richard J Ellis, Sarah E Chadburn, and Martin G De Kauwe</i>	751
VOLUME 5: SOIL PHYSICS	
Soil structure & mechanics	
Soil structure <i>Steffen Schlüter and John Koestel</i>	1
Aggregation <i>Teamrat A Ghezzehei</i>	8
Porosity and pore-size distribution <i>John R Nimmo, Sheela Katuwal, and Maik Lucas</i>	16
Pore-scale modelling of flow and transport phenomena in soils <i>Kirill M Gerke and Marina V Karsanina</i>	25
Soil texture: Its relevance, measurement and representation internationally <i>Attila Nemes</i>	35
Soil tilth <i>Thomas Keller, Douglas L Karlen, and Paul D Hallett</i>	48
Crusts and seals: Structural <i>Shmuel Assouline and Sally Thompson</i>	57
Soil mechanics <i>Markus Berli and Paul D Hallett</i>	69
Compaction <i>JJH van den Akker, L ten Damme, M Lamandé, and Thomas Keller</i>	85
Bioturbation—Physical processes <i>Siul Ruiz, Paul D Hallett, and Dani Or</i>	100
The reinforcement of soil by plant roots <i>Alexia Stokes and Anil Yildiz</i>	115
Physical effects of soil salinity <i>David Russo</i>	123
Shrink-Swell processes in soils <i>Pascal Boivin</i>	139
Water retention	
Water properties <i>N Lu, C Zhang, and D Hillel</i>	146
Water potential <i>Dani Or, Markus Tuller, and Jon M Wraith</i>	159
Water content and water potential measurement <i>Wolfgang Durner</i>	168
Soil water retention and characteristic curve <i>Markus Tuller and Dani Or</i>	187
Soil water repellency <i>Jörg Bachmann and Marc-Oliver Goebel</i>	203

Flow & transport processes

Aeration	216
<i>Rodney T Venterea and Dennis E Rolston</i>	
Capillarity	225
<i>Dani Or and Markus Tuller</i>	
Darcy's law	240
<i>Conrad Jackisch and Eva Kröner</i>	
Diffusion	247
<i>TKK Chamindu Deepagoda and Shoichiro Hamamoto</i>	
Hydrodynamics in soil	256
<i>Ty Ferre and Art Warrick</i>	
Thermodynamics of soil water	262
<i>Pieter H Groenevelt</i>	
Immiscible Fluids	271
<i>Yukie Tanino and Dubravka Pokrajac</i>	
Overland flow	287
<i>Tammo S Steenhuis, Rajith Mukundan, and Seifu A Tilahun</i>	
Direction-dependency of soil hydraulic and mechanical properties	294
<i>Steffen Beck-Brochsisitter, Heiner Fleige, Jose Dörner, and Rainer Horn</i>	
Macropores and macropore flow	306
<i>Nicholas Jarvis and Mats Larsbo</i>	
Unstable preferential flow in porous media	314
<i>Naaran Brindt, J-Yves Parlange, and Tammo S Steenhuis</i>	
Leaching processes	321
<i>Brent Clothier and Steve Green</i>	
Colloid transport	336
<i>Yan Jin, Chongyang Shen, and Volha Lazouskaya</i>	
Scaling of transport properties	353
<i>Robert Ewing and Behzad Ghanbarian</i>	
Soil influence on groundwater	364
<i>David Rudolph and Edwin Cey</i>	

Thermal properties and behaviour

Temperature effects of soil hydraulic properties	379
<i>Jan W Hopmans and Robert Horton</i>	
Heat and vapor transfer	385
<i>Sunny Eng Giap Goh, Joshua L Heitman, and Robert Horton</i>	
Radiation Balance	393
<i>Jerry L Hatfield, Kaitlin Togliatti, Thomas J Sauer, and John H Prueger</i>	
Freezing and thawing cycles	400
<i>Alan W Rempel</i>	
Arctic permafrost	410
<i>Julia Boike, Andrey Abramov, Katrina E Bennett, and Lars Kutzbach</i>	
Permafrost and cold region hydrology	419
<i>Masaki Hayashi and Ylva Sjöberg</i>	

Sensing Techniques

Soil water sensing by neutron scattering	427
<i>Steven R Evett</i>	

Time-domain reflectometry <i>GC Topp and Ty Ferre</i>	436
Geophysical methods for soil applications <i>Sarah Garré, Guillaume Blanchy, David Caterina, Philippe De Smedt, Alejandro Romero-Ruiz, and Nataline Simon</i>	444
Non-invasive imaging of soil processes <i>Craig J Sturrock</i>	459
Hydrology & water balance	
Soil processes in the hydrologic cycle <i>Cosimo Brogi, Harry Vereecken, Heye Reemt Bogena, and Luca Brocca</i>	469
Global water cycle from a soil perspective <i>Michael H Young and Dani Or</i>	482
Water evaporation from bare soil <i>Peter Lehmann</i>	490
Evapotranspiration <i>Yuting Yang</i>	501
Plant available water <i>Quirijn de Jong van Lier, Sally D Logsdon, Everton Alves Rodrigues Pinheiro, and Paulo Ivonir Gubiani</i>	509
Plant-water relations <i>Ian C Dodd, Andrew D Hiron, and Jaime Puértolas</i>	516
Water use efficiency: A review of spatial and temporal variability <i>Simone Fatichi, Athanasios Paschalis, Sara Bonetti, Gabriele Manoli, and Christoforos Pappas</i>	527

Abstract

Soil structure is the spatial arrangement of particles, pores and organic components of soil. It influences many processes in soil and is at the same time shaped by them. Soil structural properties are therefore important indicators for soil functions. This chapter explains the links between soil structure and soil functions, describes important drivers of soil structure dynamics, provides an overview of methods to characterize soil structure at different spatial scales and discusses implications for modelling.

Key points

- Dichotomy of pore structure and solid structure.
- Constituents, functions and measurement techniques of soil structure are summarized with respect to spatial scale.
- Implications for models of water and matter cycles.

Introduction

Soil structure has been defined as the spatial heterogeneity of different components and properties of soil (Dexter, 1988). This comprises the spatial arrangement of both solid constituents and pores at various scales, e.g., from the way in which flocculated clay platelets assemble at the nm scale to earthworm burrows that stretch down the entire soil profile at m scale. There are two different approaches of characterizing soil structure: either by the size, shape and grade of soil aggregates as diagnostic features or by the volume fraction, size and connectivity of pores (Vogel et al., 2021). Both have merits in understanding soil functions as all processes in soil occur in pores and at pore surfaces, but it is the binding forces of particles that retain pore shape and connectivity. A comparison of scales is given in Fig. 1. Pores are typically classified according to their size and resulting functions. Macropores have a diameter larger than 10–50 μm (Blume et al., 2016), in which gravity exceeds capillarity. These pores drain quickly and are important for soil aeration. In mesopores, water is held against gravity by capillary forces that are weak enough to be overcome by plants to extract it. Mesopores not only constitute the reservoir of plant-available water, but also the habitable pore space for most microorganisms, many of which are restricted to aqueous environments. Micropores ($<0.2 \mu\text{m}$ according to German soil classification, Blume et al., 2016) are too small to accommodate most bacteria and water is too tightly bound in it to be extracted by plants (matric potential $<-1500 \text{ kPa}$). Different subcategories and size limits are used by other classification systems and disciplines, e.g., soil micromorphology or colloid and surface chemistry. Although most studies report macropores to be greater than 10–50 μm in size, some studies have used a cut-off as large 1000 μm (Luxmoore, 1981). Likewise, micropores are generally less than 0.2 μm , but the size range used as the cut-off can be as large as 10–30 μm (Luxmoore, 1981; Brewer, 1964). Pores are also classified into primary (or textural) pores, which are voids resulting from assembly of irregularly-shaped particles, and secondary (or structural) pores resulting from aggregation and structure-forming processes. These structural pores are the reason why a fine-textured, loamy soil can have an equal or even greater saturated hydraulic conductivity than a coarse-textured, sandy soil.

Soil structure also manifests itself as the spatial variability of the stability against mechanical stress. Different binding agents act at different scales and have different strengths, arising from very stable polyvalent cations and organo-mineral associations at the molecular scale, to roots and hyphae that enmesh particles at mm-cm scales. As a result, soils harbor a hierarchy of failure zones. When these are activated by mechanical stress, e.g., through tillage or sieving, soils crumble into fragments, which have traditionally been termed clods, peds or aggregates. Further information can be found in the articles on Aggregates and Tilth found in the encyclopedia.

Soil structure and soil functions

Many processes in soil are sensitive to soil structure and many soil functions depend on it (Figs. 1 and 2). The pore structure provides the pathways for water and matter fluxes, and the habitat for soil biota. In addition, the pores and pore-solid interfaces shape chemical reaction patterns in space, altogether giving rise to a variety of micro-environmental conditions encountered in soil. At the same time, the soil structure is shaped by many biotic and abiotic processes leading to various feedback mechanisms between soil structure and the processes occurring in it (Fig. 2). These feedbacks are the reason why soil structure can be used as an indicator of many essential ecosystem functions of soil like plant growth, maintenance of biodiversity, carbon storage, organic matter turnover or water retention (Rabot et al., 2018).

Due to the utility of soil structure in characterizing soil quality or health, scores of what constitutes “good” or “poor” soil structure have been developed for field assessment. These have been derived by regression analysis of the properties or interest, e.g., crop yield, infiltration capacity, with readily available proxies for soil structure such as bulk density or air capacity (Rabot et al., 2018). Bulk density is a very easy to obtain parameter defined by the mass of dry soil in a given volume. With compaction, more soil is present in a given volume at the expense of lost porosity, so density increases. As bulk density lumps all pores together and is influenced by soil texture, it can be a poor indicator of soil structure functions such as root growth (Kaufmann

Fig. 1 Comparative scales in soil structure including abiotic and biotic constituents as well as a selection of associated soil functions. Size cut-offs for particles and pores according to German soil taxonomy (Blume et al., 2016).

Fig. 2 Interactions between soil structure, soil biota, water and matter, as well as the soil functions that are maintained by these interactions.

et al., 2010). That is why other indicators like the degree of compactness that accounts for texture (Reichert et al., 2009), or more descriptive measurements of pore structure like the S-index (Dexter, 2004) have been advocated. Useful information on soil structure can also be estimated from water retention characteristics; particularly at critical cut-off points such as field capacity and wilting point. Mechanical properties of soil can also characterize how soil structure affects root growth and burrowing fauna. Therefore, combined mechanical and hydrological measurements, such as the least limiting water range (Da Silva et al., 1994), have been developed.

Soil structure dynamics

Soil structure is not static, but continuously modified by various processes compiled in Fig. 2. Weather has a large impact, primarily through the action of wetting and drying the soil that can cause structure to collapse or disaggregate under wetting, and crack under drying. In tilled agricultural soils, cultivation fragments the soil to produce tilth that can rapidly change depending on the stability of the soil. A common measurement of soil stability assesses the breakdown of aggregates through laboratory-imposed stresses of rapid or slow wetting, or mechanical perturbation.

Soil biota including plant roots, earthworms, termites, ants and others have the strength to reshape the pore space to explore the soil for resources and protection. This mixing process called bioturbation is a major driver for soil structure dynamics (compare Fig. 3a and b). Soils harbor an earthworm population of some 100 kg ha^{-1} , that can easily incorporate several tons of annual litter fall per ha (Schaefer and Schauer mann, 1990). In addition, plant roots and soil fauna have an indirect effect on soil structure by enhancing its stability through the release of organic compounds, gluing agents and physical enmeshment by roots, hyphae and plant residues. The soil carbon brought about by these organic amendments often correlates positively with soil structural stability, when land use and soil management have been stable over long periods of time, e.g., continuous forest, pasture, or tillage type. The soils have then evolved into a state in which structure stabilization by organo-mineral associations and organic matter stabilization by physical protection within the soil structure has reached an equilibrium. For a given type of soil management, correlation between organic matter and structural stability can be highly soil-dependent, with texture playing a major role. In many cases, a certain threshold level of organic matter is necessary before soil structure begins stabilizing (Fig. 4). The threshold value tends to increase with increasing soil clay content, suggesting that a critical amount of organic matter per unit mineral surface area must be exceeded before effective stabilization occurs.

Crack formation through shrinking and swelling of 2:1 clay minerals is an important abiotic structure-forming process (compare Fig. 3c). Once these desiccation cracks have been initiated in a drying event, they can be partially refilled by other particles, which is a dominant pedogenesis process in shrinking soils such as vertisols. In addition, clay platelets at the crack surfaces get reoriented by compression with the next swelling event, so that the failure zones persist and get reactivated upon the next drying events. Freezing and drying cycles can have a similar effect on soil structure, as water migrating to the freezing front dries out the soil elsewhere. In addition, when ice expansion leads to local pressure build up, it can lead to rupture and soil fragmentation.

In addition to naturally occurring biotic and abiotic structure forming processes, tillage and other soil management-induced processes can modify soil structure, sometimes unintentionally. The main goal of soil tillage, besides weed control and

Fig. 3 Intact soil structure scanned with X-ray at a resolution of 20 μm . The samples were taken in (from left to right): Bad Lauchstädt, Germany (grassland, topsoil, 12% sand, 68% silt, 20% clay), Garzweiler, Germany (crop rotation, below plow layer, 5% sand, 81% silt, 14% clay), Hadera, Israel (citrus orchard, topsoil, 65% sand, 16% silt, 19% clay) and Kühnfeld, Halle, Germany (continuous maize, conventional tillage, topsoil, 63% sand, 25% silt, 12% clay). The annotated structure features comprise: (a) empty and re-filled earthworm burrows, (b) roots and root channels, (c) desiccation cracks, (d) plant residues, (e) hypothetical failure zones, (f) primary pores between particles, (g) soil matrix and (h) primary particles.

Fig. 4 Relation between structure stability and organic matter content in soil with varying texture. Structure stability was measured as aggregate stability to wet sieving (Douglas and Goss, 1982; Haynes and Beare, 1996). Reproduced with permission from Haynes RJ and Beare MH (1996) Aggregation and organic matter storage in Meso-thermal, humid soils. In: Carter MR and Stewart BA (eds) *Structure and Organic Matter Storage in Agricultural Soils*, p. 232. Boca Raton, FL: CRC Press. Redrawn from Douglas JT and Goss MJ (1982) Stability and organic matter content of surface soil aggregates under different methods of cultivation and in grassland. *Soil & Tillage Research* 2: 155–175. doi: 10.1016/0167-1987(82)90023-X.

incorporation of plant residues, is to loosen the soil and create a seedbed. Soil compaction may arise during land management. This can be intentional, e.g., rolling for soil reconsolidation after sowing, or unintended from machinery or livestock. Highly compacted soils have decreased pore space and connectivity, leading to poor aeration and greater mechanical resistance to root growth. Other land management practices may change soil structure and its stability, either as the primary goal or a secondary impact. This includes liming, which aims to flocculate clay and enhance cementation of particle contacts through cation bridges. Liming does this by replacing monovalent K^+ or Na^+ cations with polyvalent Ca^{2+} cations on reactive surfaces. Any management choice that increases carbon stocks or prevents the reduction of carbon stocks by protection against soil erosion, such as catch crops and manure application can have a similar, beneficial effect on the stability of soil structure.

Methods of structure analysis

Soil structure is an important parameter in soil survey and classification. Analyzing soil structure is inherently difficult due to the opaque nature of soil. Over the past decade, there has been a surge in the use of non-invasive methods like X-ray tomography that can visualize pore space, but this is limited to research laboratories and very expensive. Non-invasive approaches make it possible to measure the 3-D arrangement of solids and pores in soils directly, but indirect approaches provide a valuable estimation. Early investigations of soil structure therefore involved analyses of soil fragments, termed aggregates, as a proxy for the 3-D arrangement of particles and pores.

The simplest examination of soil structure can be done in the field from a visual inspection of soil aggregates that have been manually extracted from the soil by experts. The criteria used in this classification scheme are type or shape, class or size, and grade or distinctness of the aggregate. Different structure types are illustrated in Fig. 5. Visual soil structure characterizations normally take place in the field, often at soil profiles in freshly dug pits for soil surveying and classification.

Visual assessments of soil structure have been extended to assess the impacts of land management practices. These shovel-based approaches are rapid and use clear keys to minimize variability between operators inherent to qualitative assessments. One approach is the Visual Evaluation of Soil Structure (Guimarães et al., 2011) which extracts a section of soil to spade depth and assesses the breakup of the soil into fragments. The abundance, distribution, shape and size of visible pores and roots growing into the fragments, and evidence of mottling, are used to provide a soil structural quality score. Visual structure characterization has the advantage of simplicity and a very low demand in technical resources. It is however hindered by subjectivity, since both the extraction of the soil aggregates as well as their classification are based on the judgement of an expert.

Soil fragments can also be extracted and investigated in the laboratory under well-defined conditions, providing greater objectivity than rapid field assays. These can either use tilth, i.e., soil already fragmented into aggregates by tillage, or aggregates isolated from the soil through mechanical agitation and sorting by size through sieving (Kemper and Rosenau, 1986). The aggregates can then be investigated as individual entities, measuring properties such as aggregate density or strength, or used to assess soil aggregate stability. Soil aggregate stability tests mimic stresses experienced in the field that destabilize soils and may lead to erosion or crusting. The different stresses and their relevance are: (i) rapid wetting to simulate intensive rainfall on dry soil that induces slaking; (ii) capillary wetting similar to groundwater rise that induces slumping; and (iii) mechanical breakdown as would occur from raindrop impact or tillage (Le Bissonnais, 1996). Mechanical breakdown is typically imposed by stirring the soil, but the use of ultra-sonication has been advocated to impose more controlled energy inputs. Very high ultra-sonication energy coupled with oxidation of the organic material can be applied to break down larger aggregates to even smaller and more stable pieces. While aggregate-based approaches of soil structure characterization are still widely in use and of great utility for assessing soil structural quality and erosion resistance, their failure to capture the original 3-D arrangement of solids and pores of intact soil brings criticism (Vogel et al., 2021).

Fig. 5 Classification of soil structure by aggregate characterization based on visual appearance. Reproduced with permission from FAO (2006) *Guidelines for Soil Description*. 4th edn. FAO: Rome.

Stemming from early research on soil genesis and classification, 2-D thin sectioning approaches were developed to retain the intact structure of soil (Bullock et al., 1985). The sections are created by taking intact specimens that are impregnated with a resin and then attached to a glass slide before being cut and ground to 10–30 μm thickness. Micromorphological examination of thin sections allows for the analyses of the spatial arrangement of pores and solids without breaking up the original soil structure into aggregates. In addition to intact pore structure, soil thin sections have the added benefit of allowing for mapping biochemical heterogeneity and the spatial distribution of microbiota with various microscopy and micro-spectroscopy techniques. The method is however associated with a large workload and limited to 2-D structure characterization. 3-D X-ray imaging has emerged as a major tool to quantify structures in natural, undisturbed soil. Based on X-ray computed tomography, previously inaccessible structural information can be quantified, such as the connectedness of individual pores or the bottleneck in the pore connection from one side of the sample to the other.

The methods for structure analyses, described above, have characteristic scales at which they can be applied (Fig. 1). X-ray imaging can visualize pores at sub-micron resolution, but only for small samples a few mm in size. By rule of thumb, the respective image resolution is presently in the range of the sample diameter divided by 1000–2000. The image resolution is expected to improve in the coming years with further developments of the detector hardware. Thin-sections visualize pores down to the thickness of the section, so typically 10–30 μm diameter. The lateral resolution of micro-(spectro)scopic imaging applied to these soil sections varies with optics and spot sizes of different techniques. Aggregate analyses in the laboratory consider aggregate diameters between some micrometers and a few centimeters. Visual soil structure inspection is limited to structures larger than a millimeter but has the advantage, that it is applicable to larger scales, i.e., up to more than 1 m at a soil profile. Geophysical methods like electrical resistivity tomography (ERT) and georadar (GPR) have been tested for soil structure mapping at the plot and field scale (10 m and more). While these methods may offer useful insights, they suffer from large ambiguities in the measurement results (ERT) or are only applicable on dry soil with low clay contents (GPR).

Implications for modeling

The structure of the soil pore-network and its stability determine how gases are exchanged and water and associated solutes and colloids are flowing under a given hydraulic gradient. It therefore needs to be reflected in models that simulate gas and water and solute movement through the soil. The nature of the pore network makes this a non-trivial task. Soil structure may be characterized by an entropy, with complete disorder as in clean sand with only primary pores at the one extreme and complete order as with a bundle of capillaries at the other. In the majority of cases, soil structures exhibit intermediary entropies, which are inherently difficult to grasp within mathematical models. Early models conceptualized soil as one of the two extremes on the entropy scale, most prominently in the form of Richards' equation and the advection-dispersion equation, which fit best to the case of maximal entropy. Later, dual and multi domain models emerged to amend some of the obvious shortcomings of these simple models. Alternative approaches have aimed at capturing the pore-network hierarchy with fractal relationships. Albeit fractal dimensions can be derived from soil structure and similar power law scaling appears in some soil hydraulic functions, relationships with which pore-structures could be derived from hydraulic functions using only fractal properties (or vice versa) are yet not available despite decades of research. Yet another approach to implement the effects of soil structure are stochastic models that view soil as a spatially correlated random field of hydraulic properties. However, commonly assumed random fields match rather poorly to e.g., hydraulic conductivity fields obtained from X-ray image data of soils. Eventually, there is often no short-cut from measuring the pore structure in individual soil samples to answer more specific questions on water, solute and air movement in this soil, such as the amount of soil by-passed under preferential flow or the volume fraction of well-aerated soil. Köhne et al. (2009) give an overview of existing water flow and solute transport model approaches for structured soil and you can read more in the articles on Pore Scale Physical Processes, Scaling and Solute Transport found in this encyclopedia.

Carbon and nutrient cycles are driven predominantly by microbes and plant roots, which in turn require specific redox and moisture conditions. Carbon and nutrient cycles in soil are therefore also intimately coupled to the exchange of gases and movement and retention of water and dissolved organic compounds (See section "Soil structure and soil functions"). For example, root growth, and therefore the supply of fresh organic matter, is guided by macropore structures and water-movements in smaller pores. Microbial communities that mineralize carbon efficiently need environments with a good balance of water supply, as the solvent of carbon substrate and nutrients, and oxygen supply, as an energetically efficient electron donor for soil respiration. Respective model simulations need to be necessarily based upon the above-discussed hydraulic models, which makes predictive modelling of carbon mineralization and the associated biology a highly complex task (Moyano et al., 2013). The same holds for models of nutrient cycles (nitrogen, phosphorus, among others), for which similar links to soil structure exist.

The fact that soil structure is constantly evolving adds an extra layer of complexity to modelling soil systems and makes it a truly challenging field of research. Models for soil structure evolution are still at the very forefront of scientific research and have only recently been emerging.

Summary and outlook

Soil structure underpins flow and transport, microbial habitats, root growth channels and mechanical behavior. It is therefore an important property of soil that affects soil quality, with stresses from land mismanagement presenting a major challenge.

Soil is said to be one of the most complex materials known. The main ingredient for this complexity is the soil structure, which compartmentalizes soil into a large number of different regions with various degrees of connections between them. This renders understanding and modelling of physical, chemical, biological or ecological processes in soil systems a challenging endeavor, as they all strongly depend on individual soil structures. At the same time, this means that knowing the soil structure is key in appraising soil functioning. Soil structure derived indicators are therefore included when classifying soil quality.

Future developments in hardware will provide improved imaging methods with which not only the 3-D physical soil structure but also the associated chemical properties and embedded soil biology can be quantified better. Promising approaches involve correlative imaging, in which two or more complementary imaging methods are superimposed (Hapca et al., 2015; Schlüter et al., 2019). Improved computational power and modelling approaches will then enable to implement this improved information on the nature of the soil pore-network into 3-D models, which will be needed to further untangle the complexity of soil systems.

Abstract

Aggregation is a vital characteristic of soil structure that affects its physical and biogeochemical properties. Aggregation results from the cohesion of primary minerals with organic or inorganic constituents. It depends on the dynamic balance between binding and fragmentation. There are two classes of aggregation. Mechanical aggregates are formed instantly by external forces and are often unstable. Hierarchical aggregates result from slow binding and are stable. Characterization of aggregation includes size, shape, stability, configuration, and their arrangement within soil. The nature of hierarchical aggregation is inferred from size separation of aggregates. Aggregate stability indicates their ability to persist under disruptive forces.

Glossary

Aggregate stability The ability of aggregates to persist under internal (e.g., rapid wetting or desiccation) and external (e.g., tillage or bioturbation) disruptive forces.

Hierarchical aggregation Binding of soil constituents by various abiotic and biotic binding factors spanning multiple scales.

Mechanical fragmentation Formation of soil aggregates by mechanical fragmentation of large clods.

Rhizodeposit Organic deposits added by living or dead roots, including short-lived root hairs, sloughed-off cells, exudates, and mucilage.

Rhizosheath An armor of soil particles that strongly binds to living roots and remains attached to the root system when pulled out of the soil and shaken vigorously.

Slaking The process of fragmentation of an aggregate by escaping entrapped air when rapidly submerged in water.

Key points

- Soil aggregates are essential features of soil structure, responsible for soil physical and biogeochemical characteristics relevant to agricultural and ecosystem functions.

- There are two broad classes of soil aggregates; aggregates formed by (a) mechanical fragmentation and (b) slow hierarchical binding of soil constituents. Mechanical fragments are formed instantly by external forces, while hierarchical aggregates are formed through the slow binding of soil constituents by various abiotic and biotic binding factors spanning multiple scales.
- The life cycle of soil hierarchical aggregation is closely associated with the biophysical dynamics of soil organic matter, including source, dynamics, and biotic-abiotic feedback. Higher-order hierarchical soil aggregation exists only when organic matter is the primary driver.
- Soil aggregation has three related characteristics: the size and shape of individual aggregates, the stability of aggregates, and the configuration and arrangement of aggregates within the undisturbed soil.
- Aggregate size separation and stability are determined through sieving and applying disruptive forces that reflect forces encountered in real field conditions.

Introduction

Soil aggregates are composite soil units formed by the cohesion of primary mineral with organic constituents that remain stable when subjected to disruptive forces. Aggregation is an essential feature of soil structure—the spatial arrangement of soil constituents and the resultant complex pore network, which spans a wide range of sizes and connectivity. The state of soil aggregation is a product of a dynamic balance of binding and fragmentation. It is characterized by the constant transfer of bound soil constituents between neighboring volume elements of aggregated soil, often bound together to form even larger and weaker aggregates. In addition, soil aggregates are more delicate than primary mineral constituents and readily respond to disturbances such as cultivation, fire, drought, flooding, and changes in vegetation. As a result, soil aggregation evolves faster than soil texture and mineralogy, which change at geologic time scales. Therefore, the evolution of soil aggregation is responsible for numerous alterations of soil physical and biogeochemical characteristics within the time frame relevant to agricultural and ecosystem functions.

Conversely, the processes responsible for aggregate dynamics, including biological activity, wetting-drying cycles, and dissolution and precipitation of soil constituents, are also directly influenced by the state of soil aggregation. There are two broad classes of soil aggregation: (a) mechanical fragmentation and (b) slow binding of hierarchical aggregates. Although mechanical and hierarchical aggregates exhibit similar morphology after separation, their functions are distinct (Fig. 1).

Fig. 1 Two main mechanisms of soil aggregation: (A) mechanical aggregation by breakdown of clods and (B) hierarchical aggregation by complex biotic and abiotic interactions.

Mechanical aggregates (fragments)

The fragmentation of large soil clods in cohesive soils, e.g., by tillage, freezing-thawing cycles, and burrowing animals, instantly creates an assemblage of differentiated *mechanical aggregates (fragments)* (Pires et al., 2017). These aggregates are readily observable in freshly prepared seedbeds (Hadas, 1997). The binding agents that hold these aggregates together vary with the soil composition and may include abiotic (clay, oxides, and carbonates) or biotic (organic matter). Their characteristic feature is that they form instantly by external forces. Mechanically derived aggregates are often unstable and revert to coarser blocks when neighboring aggregates coalesce by capillary attraction during wetting-drying cycles (Ghezzehei and Or, 2000).

Hierarchical aggregates

The slow binding of soil constituents by various abiotic and biotic binding factors spanning multiple scales results in *hierarchical aggregates* (Tisdall and Oades, 1982). Electrostatic bonding of clay aluminosilicate platelets (flocculation) forms $<2\ \mu\text{m}$ **clay domains**, the lowest element in the hierarchical order of soil aggregation. Flocculation is the balance of both repulsive and attractive forces. Repulsion arises due to similarly charged ions attached to clay surfaces. An attractive force emerges when the distance between clay platelets is small enough that opposing sides share ions. The distance is dependent on the hydrated size of ions. With their small hydration spheres, divalent cations such as Ca and Mg promote flocculation. On the other hand, the large, hydrated volume of monovalent ions such as Na and Li causes the dispersion of clays.

Further bonding of stable clay domains and silt particles results in the formation of 2–20 μm clusters. Colloidal aluminosilicates and Fe and Al oxides are the primary binding agents at this scale (Totsche et al., 2018). In addition, the desiccation of colloidal organic molecules derived from root exudation and microbial extracellular polymeric substances (EPS) can form hardened glue that binds clusters (Tisdall and Oades, 1982). Clusters are also referred to as medium-sized microaggregates.

The binding of clusters and fine and medium-sized sand grains results in the formation of large (20–250 μm) microaggregates. The nature and persistence of binding agents at this scale vary considerably with soil type and management but generally include processed organic macromolecules, polyvalent metal cation complexes, oxides, and highly disordered aluminosilicates (Totsche et al., 2018).

Macroaggregates ($>250\ \mu\text{m}$ but typically not bigger than several millimeters) constitute the largest class in the hierarchy. The bonds that hold macroaggregates together are usually weaker and more transient than those that bind microaggregates. These include enmeshing by hyphae and root hairs or binding by microbial EPS and root exudates (polysaccharides). Macroaggregates ($>250\ \mu\text{m}$) are formed during the rapid mineralization of fresh organic matter inputs. Microaggregates develop gradually within macroaggregates (Tisdall and Oades, 1982) as more of the organic matter is mineralized and forms a more stable association with the mineral surfaces.

Large soil clods ($>25\ \text{mm}$) are not considered part of the hierarchical aggregation concept. Such lumps need not contain lower-order aggregates and are typically formed by the desiccation of soils with a large fraction of clays, oxides, or carbonates. In agricultural soils, disruption of stable hierarchical aggregates by tillage and subsequent compaction by machinery can form dense clods (Dexter, 1988).

The study of soil aggregation and its function is usually preceded by the separation of (sieving) aggregates from bulk soil. Therefore, mechanical fragments are rarely distinguished from biologically derived hierarchical aggregates owing to their similarities in appearance and size. Moreover, sieving removes the spatial organizational context that aggregates occupy in soil structure. This ambiguity in our conceptual definition of soil aggregates conceals significant differences in the genesis and ecological functions of soil aggregates formed in natural and managed soils (Or et al., 2021, and references cited therein). This ambiguity is particularly crucial in managed soils subjected to reduced tillage, in which both forms of aggregate formation can coexist and interact.

Life cycle of hierarchical aggregates

Higher-order hierarchical soil aggregation exists only when organic matter is the primary driver (Tisdall and Oades, 1982). Therefore, *the hierarchical conceptual model plays a crucial role in explaining soil organic matter dynamics*. Conversely, the life cycle of soil aggregation is closely associated with the biophysical dynamics of soil organic matter (SOM), including source, dynamics, and biotic-abiotic feedback.

Sources of organic matter for aggregation

For most natural ecosystems, the predominant source of SOM is primary production by local vegetation. Other forms of organic matter inputs from outside sources (e.g., manure and compost inputs, deposition of eroded sediments, dissolved or suspended organic matter in surface or subsurface streams of water, and feces and remains of fauna) may play a role in specific conditions. Root-derived SOM inputs dominate overall stocks and aggregate-associated carbon (C) (Rasse et al., 2005). Roughly half of photosynthetically fixed plant C is allocated belowground as root tissues, rhizodeposits, and root respiration (Nguyen, 2003). A significant portion of the aboveground biomass is processed and lost before being incorporated into the underlying soil by mixing

(e.g., earthworms, rodents or agricultural practices) or leaching as dissolved organic matter (DOM). For example, the leaf residue of forest floors is degraded in the litter layer, with only a small fraction entering the underlying soil (Crow et al., 2009). The surface-applied residue is decomposed mainly in situ, with a small fraction getting incorporated in subsurface pools in the form of dissolved organic matter (DOM) that later gets incorporated into mineral-associated fractions (silt and clay) (Gale and Cambardella, 2000). Moreover, root-derived C persists for a much longer time in soils (Rasse et al., 2005). The physical form of root-derived organic matter and the environmental conditions it encounters in aggregated soils account for the majority of this preferential stability. The centrality of roots in soil aggregation is apparent when one gently pulls out or excavates the root system of most plants. Soils inhabited by dense and fine root systems, such as ryegrass, promote stable macroaggregates that withstand post-tillage collapse by wetting and drying (Cockroft and Olsson, 2000). Furthermore, the degree of aggregation is correlated with root density (Fig. 2).

Organic matter forms and transformation relevant to aggregation

A key feature of the organic matter storage that distinguishes well-aggregated soils is the relative quantity of particulate organic matter (POM) (Gale and Cambardella, 2000). The amount of soil incorporated in macroaggregates is correlated with macroaggregate-associated POM in undisturbed and restored prairie soils (Jastrow, 1996). Long-term no-till treatment or restoration to natural vegetation can restore the POM concentration to native levels over decades in some environments. Fresh POM input triggers the rapid formation of macroaggregates on a time scale of several weeks. The rapid decomposition of labile POM and the accompanying soil-binding effect of microbial EPS and hyphae are responsible for the formation of macroaggregates. Scanning Electron Microscopy (SEM) images of microaggregates developed in native soils reveal that many 100–200 μm microaggregates retain the elongated shape of root residues and release visible POM cores upon ultrasonic disruption (Tisdall and Oades, 1982). Smaller ($\sim 90 \mu\text{m}$) and presumably more processed microaggregates lose their elongated shape but retain some traces of the root POM residue or contain voids that once were occupied by roots. Moreover, high-resolution X-Ray $\mu\text{-CT}$ images of stable macroaggregates ($\sim 5 \text{ mm}$) reveal root-derived POM in their cores (Kravchenko et al., 2015). Macroaggregates are typically weak and can easily break if the soil is disturbed, e.g., by tillage or slaking. In macroaggregates that continue to mellow without disturbance, POM decomposition progresses slowly and may result in stable microaggregation within the volume previously occupied by larger macroaggregates. Therefore, *the cultivation of undisturbed or native soils preferentially degrades weak macroaggregates, resulting in the mineralization of the organic binding agents and rapid loss of organic matter content* (Tisdall and Oades, 1982).

Living roots also contribute to aggregation by depositing large amounts of rhizodeposits, including short-lived root hairs, sloughed-off cells, exudates, and mucilage. Mucilage and root hairs have soil-binding characteristics, often credited with soil-binding on root surfaces. This specialized form of aggregation, armoring of living roots by mineral-mineral and mineral-root attachments, is known as the *rhizosheath* (Read and Gregory, 1997). Rhizodeposits also fuel rhizosphere microbial activity and the production of soil-binding EPS and fungal hyphae. Roots are also responsible for frequent and pronounced wetting-drying cycles in the rhizosphere. The accompanying back-and-forth motion of water menisci can mobilize and reorient clay particles resulting in the tight coating around roots (Dorioz et al., 1993). In addition, the transport of soluble organic molecules and their subsequent preferential deposition at inter-particle contact points results in a strong gluing effect in the rhizosheath.

Fig. 2 Influence of organic matter content and type on formation and stability of microaggregation and macroaggregation (using data from Tisdall and Oades (1982)).

Biotic and abiotic feedback

The environmental conditions of soils are as crucial as the chemical nature of soil organic matter in regulating soil C dynamics and associated biogeochemical cycles (Schmidt et al., 2011). Soil organic matter is a continuum of materials of varying complexity, undergoing constant alteration. Within this framework, soil aggregates play an essential role in controlling the environmental conditions that in turn control organic matter transformations. Hierarchical soil aggregation creates a complex three-dimensional pore network with relatively porous inter-aggregate spacing and a tight interior. This arrangement leaves a relatively wet and oxygen-deprived core that limits the degradation of SOC. In addition, the organic molecules released by plant roots and microbes alter soil water retention characteristics. This aggregation-driven hydrodynamics results in spatial segregation of microbial communities and contrasting nutrient consumption patterns, with an overall slowdown of decomposition.

Characterization

The concept of soil aggregation implies three related characteristics (Martin et al., 1955): (a) the size and shape of individual aggregates, (b) the stability of aggregates, and (c) the configuration and arrangement of aggregates within the undisturbed soil. Aggregate size separation is used to infer the nature of the hierarchical aggregation, and aggregate stability indicates the ability of aggregates to persist under internal (e.g., rapid wetting or desiccation) and external (e.g., tillage or bioturbation) disruptive forces. Size separation of aggregates typically employs sieving in a dry or wet state and separates only those aggregates that withstand the sieving action. However, there are no straightforward methods for characterizing the morphology and size of undisturbed aggregates as they exist in their natural state (see “Imaging” section). A possible exception is the dry separation of mechanical aggregates, in which the aggregates are already pre-formed during fragmentation. Therefore, aggregate stability and aggregate size are practically considered together. Both have been adopted as quantitative indicators of soil fertility and health (Lehmann et al., 2020), and several standardized methods exist. The disruptive forces used to characterize aggregate sizes and stability are chosen to reflect forces encountered in real field conditions or to disrupt specific orders within the aggregate hierarchy (Dexter, 1988). The destruction of bonds that bind aggregates of a certain hierarchical order is accompanied by the destruction of all higher orders.

Dry aggregate size distribution

Dry aggregate stability mimics the resistance of tilled agricultural soils to wind erosion. In most cases, the airflow speed past soil aggregates is not strong enough to disintegrate aggregates (Nimmo and Perkins, 2002). However, the abrasive energy of wind-blown loose soil particles and smaller aggregates can damage and break down aggregates. Mechanical separation of aggregates using stacks of sieves or a rotary (tumbling) sieve simulates wind-driven abrasion. The resulting aggregate separates are typically smaller than the mechanical aggregates that exist on tilled soil beds. However, the fraction of soil that remains in intact aggregates after a prescribed mode of dry abrasion serves as a quantitative indicator of resistance against wind erosion. As aggregates break down to <0.8 mm in size, they are small enough to be moved by wind erosion by creeping across the surface or saltation, with further break down resulting in wind erosion of aggregates by suspension in air.

Water stable aggregation

Water stability refers to resistance to two distinct disruptive forces (Nimmo and Perkins, 2002). First, wetting of initially dry soil is prone to disintegration by the pressure of entrapped air that builds inside the engulfed pores and the swelling of clays (*slaking*). The resistance to slaking is an important indicator of soil stability during rapid wetting and resistance to raindrop splash. Second, the stability of aggregates against flowing water reflects the resistance of soils to sheet erosion and the stability of soil structure (pores and pore connectivity) during wetting and redistribution of soil water. Generally, water stability can be determined using a single sieve (e.g., 250 μm or 2000 μm) or a nest of sieves and subjecting soil aggregates to up-and-down motion while fully submerged underwater. When dry aggregates are subjected to wet sieving, the resulting stability reflects stability against both slaking and flowing water. When dealing with weak aggregates, the aggregates are prewetted under vacuum or by capillary action to eliminate the action of slaking. In addition, using a stack of sieves, one can fractionate the soil volume into silt-clay (0–53 μm), micro-aggregates (53–250 μm) and macroaggregates (>250 μm). However, the stack of sieves method does not distinguish between the separated particles of a certain order and similarly sized particles contained within stable particles of higher order.

When aggregate size classes are determined by either dry-sieving or wet-sieving, as described above, the distribution is often described in terms of arithmetic mean weight diameter (MWD) or geometric mean weight diameter (GMD). MWD implies normal distribution of soil aggregates, while GMD is associated with a log-normal distribution. The latter is consistent with most soils. They can be calculated by the equations:

$$MWD = \sum_{i=1}^n \omega_i \bar{x}_i, \text{ and} \quad (1)$$

$$GMD = \exp \left[\frac{\sum_{i=1}^n \varpi_i \log(x_i)}{\sum_{i=1}^n \varpi_i} \right], \quad (2)$$

to account for the number of sieve sizes used, n , the mean diameter of the i th sized sieve, x_i , and the portion of the initial sample weight retained on the i th sized sieve, ϖ_i after dry-sieving or wet-sieving.

Aggregate strength

Generally, aggregate strength decreases with size. Specifically, aggregates of higher hierarchical order (e.g., macroaggregates) are weaker than the lower-order aggregates contained within them. Therefore, the tensile strength of an aggregate of a certain order indicates the strength of the bonds between aggregates of lower hierarchical order (Dexter, 1988). Tensile strength is measured by crushing a single aggregate between two plates. The top plate is lowered at a constant speed while monitoring the applied force. This causes the soil aggregate to bulge outwards, creating a tensile stress at its center. The strength, TS , is calculated as a ratio of the force, F at failure to the cross-sectional area of the aggregate normal to the direction of the force. As soil aggregates have an irregular shape, the calculation of TS is not straightforward, but a generally accepted approximation is:

$$TS = 0.576 \frac{F}{\bar{d}^2}, \quad (3)$$

where $\bar{d}$ is the geometric mean diameter of the soil aggregate in the x-y, x-z and y-z directions (Dexter, 1988). Various equations have been proposed to calculate soil aggregate strength, including based on the energy of fragmentation. The statistical variability of soil aggregate strength and the change in strength with aggregate size can be used to assess the friability of soil.

Fractionation of organic matter in aggregated soils

Understanding the role of soil aggregation on organic matter persistence and turnover rate requires separating the bulk SOM into fractions that reflect its distribution within the hierarchical orders. There are several methods available (Poeplau et al., 2018). The purpose of these methods is to sequentially break the bulk soil into components that reflect different modes of organic matter storage within and between aggregates. Generally, the bulk soil is separated into different aggregate size classes by gentle shaking or sieving. Then, the free (particulate) organic matter is separated from the aggregates (soil particles) within each size by floatation. Variations of methods use water (density of 1 g/cm³) or other denser fluids. The dense aggregates separated in the previous step are further broken down by the application of ultrasonic energy or chemical dispersion using Na solution and separated into different size sub-classes. The material within each class in the previous step is further separated into free organic matter and heavy fraction by floatation. Ultimately, these methods yield free organic matter (usually assumed to be particulate) contained within each aggregate size class and organic matter associated with the mineral fraction in each size class.

Imaging

Scanning Electron Microscopy (SEM) is widely used to visualize the arrangement of soil constituents at multiple scales. SEM micrographs of aggregates acquired at appropriate magnifications are the foundations for the hierarchical soil aggregation concepts (Tisdall and Oades, 1982). However, SEM visualizes only the exposed surfaces of aggregates. In contrast, X-ray CT and thin-section microscopy provide access to the internal structure of individual aggregates. For example, CT images of large macroaggregates have revealed fragments of root residence that presumably fuel the aggregation process (Kravchenko et al., 2015). X-ray CT is the only tool with the potential to visualize aggregates and their configuration and arrangement within bulk soils. Visualizing mechanical aggregates within repacked soil columns has been successful (Aravena et al., 2011). However, visualizing hierarchical aggregates within undisturbed soils has not been successful yet (Koestel et al., 2021).

Functions and interpretations

The operational definition of soil aggregation varies with the functions of interest and does not usually coincide with the mode of formation (Or et al., 2021). For example, in agronomy, aggregation may refer to *tilth*—a favorable friable state of seedbed resulting from mechanical fragmentation by tillage (Hadas, 1997)—or the resilience of hierarchical aggregates in minimally disturbed agricultural soils (Six, 2004). In soil conservation, aggregation explains the resistance to degradation by erosion and nutrient losses. From a biogeochemical perspective, aggregates are hot spots of microbial activity and biodiversity, with the elevated nutrient cycling within the aggregate environment liberating nutrients locked up in the organic matter. However, aggregates also provide environmental protection for organic matter and associated nutrients against rapid mineralization by constraining oxygen availability and accessibility to microbial attack (Keiluweit et al., 2016). Because soil aggregation is governed by chemical, physical, and biological factors and influences multiple soil functions, it has emerged as one the key indicators of *soil health* (“the continued capacity of soil to function as a vital living ecosystem that sustains plants, animals, and humans”) (Lehmann et al., 2020).

Biogeochemical functions

Soil aggregation controls biogeochemical rates by influencing the size and connectivity of intra- and inter-aggregate pores and associated environmental variables, including wetness, aeration, and temperature (Schmidt et al., 2011). Experimental and modelling studies of soil aggregates revealed that the distribution of aerobic and anaerobic microbial activities, development of anoxic conditions, and microbial diversity are tightly coupled with the 3D flow and transport patterns within and between aggregates (Keiluweit et al., 2016).

The microaggregates formed within macroaggregates significantly reduce the turnover rate of their C by (a) physically isolating POM with extracellular polymeric substances (EPS) and clay coatings, (b) formation of anaerobic cores, (c) fostering tighter association with mineral fractions, and (d) alteration of C chemical structure (Rasse et al., 2005). Based on these observations, soil C can be conceptually partitioned into slow (micro-aggregate associated) and fast (free and macroaggregate associated) pools of C. Standardized procedures for the separation of macro- and micro-aggregates, particularly microaggregates within macroaggregates, are described in a previous section.

Therefore, depending on the unique biophysical conditions, aggregates can act as stable reservoirs of organic matter inputs (Jastrow, 1996) or biogeochemical hotspots responsible for increased greenhouse gas emissions.

Resistance to degradation

In addition to protecting soil organic matter, soil aggregation also provides resistance against the physical degradation of soils. The hierarchical model of soil aggregation also implies that smaller aggregates exclude large pores and are, therefore, denser. This porosity exclusion principle further suggests that larger aggregates are more porous and weaker because they contain large gaps between smaller and denser aggregates within them (Dexter, 1988). These ideas explain the resistance of aggregated soils to compaction and erosion.

Flow and transport

Soil aggregation has a profound effect on the size, distribution, and connectivity of soil pores. Therefore, aggregation also plays a direct role in water flow and the transport of gases, heat, and solutes. Moreover, alteration of the state of aggregation is a primary driver of alterations in flow and transport properties. Direct information about aggregate characteristics and the degree of aggregation are not directly represented in current mathematical and numerical models of flow and transport. However, the effects of aggregation are indirectly represented as bulk density, porosity, water retention characteristic, hydraulic conductivity, and aeration. For example, post-tillage fragmentation leads to the bimodality of pore size distribution, which is typically represented by dual-porosity and dual-permeability hydraulic function. In this case, the large inter-aggregate pores drain readily but act as fast conduits for infiltration and drainage when fully saturated. Inter-aggregate pores also serve as fast pathways for gas exchange. The intra-aggregate pores are usually smaller and retain moisture for more extended periods. In contrast, the effect of hierarchical aggregation of undisturbed soils on hydraulic functions is less pronounced (Koestel et al., 2021) because in situ formed aggregates do not produce large inter-aggregate pores.

Summary and outlook

Soil aggregation is a product of biological, chemical, and physical soil factors and processes that also exerts important feedback on these driving processes. Soil aggregation is recognized as a key indicator of soil health. However, several open questions remain regarding its definition and characterization. Current methods of characterization lack the ability to distinguish between aggregates formed by fragmentation from hierarchical aggregates formed primarily by bonding. These two processes are not independent of each other, with considerable interaction. Moreover, aggregates separated by sieving and other mechanical disturbance do not necessarily reflect the nature of intact aggregates as they exist in undisturbed soils. It is possible that the undisturbed soil contains soil constituents held by a continuum of binding energies. Thus, the aggregates that are the basis for much of our knowledge about soil aggregation are partially formed during the sieving process (Young et al., 2001). Recent advances in high-resolution 3D X-ray imaging hold promise in enabling in situ visualization and characterization of soil aggregation. Direct and quantitative links between the characteristics of soil aggregates and soil biological and physical functions are not fully developed yet. Although aggregation is recognized as a dynamic soil property, modelling the aggregation evolution and the resulting effects on soil functions and ecosystem models is still in its infancy.

Abstract

Porosity, the fraction of soil volume not occupied by solids, is relatively easy to conceptualize and measure. Pore-size distribution is a complex topic, in part from the lack of a clear and unique concept of a soil pore as a discrete object. Available tools for evaluating pore-size distribution involve traditional conventions and operational definitions applied to hydraulic property characterizations, as well as more recently developed imaging techniques. Application of these tools can provide effective characterizations of the pores and pore space that lead to an understanding of the relation between pore characteristics and soil functions.

Key points

- Porosity is a fundamental characteristic of soil that is straightforward to define and measure.
- The precise delineation of a pore and its characteristic size requires artificial, subjectively-established distinctions.
- Several methods that rely on different assumptions are available to measure the pore-size distribution of a soil.
- The quantified porosity and pore-size distribution are valuable for assessing diverse functions and properties of soil.

Introduction

The pore space is that portion of the soil's volume that is not occupied by or isolated by solid material. Its basic character affects and is affected by critical aspects of almost everything that occurs in the soil: movement of water, air, and other fluids; transport and reaction of chemicals; and residence of roots and other biota. By convention the definition of pore space excludes fluid pockets that are totally enclosed within solid material—vesicles or vugs, for example, that have no exchange with the pore space that has continuity to the boundaries of the medium. Thus we consider a single, contiguous pore space within the body of soil. In general, the pore space has fluid pathways that are tortuous, variably constricted, and highly connected. Fig. 1 shows example images of soil pore space at three different scales.

The pore space is often considered in terms of individual pores—an artificial concept that enables quantifications of its essential character. Traditionally in soil science and hydrology, pores have been conceptualized, measured, and applied with respect to the fluids that occupy and move within the pore space. Recent advances in imaging techniques have facilitated additional types of characterization in terms of observable geometry and topology.

Fig. 1 View of a soil profile (loess soil) from an agricultural field at the Garzweiler mining area, Germany. The soil has pores of various sizes, shapes, and modes of origin. The image within blue rectangle is an X-ray computed tomography image of a slice of soil column obtained from the profile, in which the dark areas represent pores and the gray areas represent the soil matrix. At the resolution of $19\ \mu\text{m}$, only structural pores are visible in the image. Within the soil are also textural pores resulting from the packing of soil particles which is illustrated by the drawing of individual soil grains within the red rectangle. The gray areas represent soil particles and the dark area pores between the soil primary particles. Photo: *M. Lucas*.

Imaging techniques, however, cannot illustrate the total extent of the pore space, for example because the high resolution needed for the smallest pores can only be achieved for small samples, which do not contain large pores. Two-dimensional images have a further limitation in that the connectivity of the pores can only be incompletely shown.

Porosity

Porosity ϕ is the fraction of the total soil volume that is taken up by the pore space. Thus it is a single-value quantification of the amount of space available to fluid within a specific body of soil. Being simply a fraction of total volume, ϕ can range between 0 and 1, and typically falls between 0.3 and 0.7 for soils. With the assumption that soil can be considered as a continuum, adopted here as in much of soil science literature, porosity can be considered a function of position.

Porosity in natural soils

The porosity of a soil depends on several factors, including (1) degree of compaction, (2) breadth of the particle size distribution (polydisperse vs. monodisperse), (3) shape and size of particles, (4) cementing, and (5) aggregation. Mathematically considering an idealized medium of packed uniform spheres, ϕ must fall between 0.26 and 0.48, depending on the packing. Spheres randomly thrown together will have ϕ near the middle of this range, typically 0.30 to 0.35. A sand with grains nearly uniform in size (monodisperse) packs to about the same porosity as spheres. In a polydisperse sand, the fitting of small grains within the pores between large grains can reduce ϕ , conceivably below the 0.26 uniform-sphere minimum. The particular arrangement required to reduce ϕ to 0.26 or less is highly improbable, however, and ϕ usually exceeds 0.30 in natural soils. Particles more irregular in shape tend to have larger gaps between their nontouching surfaces, thus forming media of greater porosity. In porous rock such as sandstone, cementation or welding of particles not only creates pores that are different in shape from those of particulate media, but also reduces the porosity as the cementing material takes up space that would otherwise be pore space. Porosity in such a case can easily be less than 0.3, even approaching 0. Cementation can also have the opposite effect. In many soils, clay and organic substances cement particles together into compacted units surrounding large pores that are mechanically stable because of the rigidity of the cemented matrix. Pure matrix material might have a 0.35 porosity within it, but the medium as a whole has additional pore space such that ϕ of the bulk soil can be 0.5 or greater. Observed porosities can be as great as 0.8 to 0.9 in certain types of soils like peats (extremely high organic matter content), Andisols (volcanic ash soils), and ice-rich permafrost.

Porosity is often conceptually partitioned into two components, most commonly called textural and structural porosity. Fig. 1 shows examples of these. The textural component is the value the porosity would have if the arrangement of the particles were random, as described above for granular material without cementing. That is, the textural porosity might be about 0.3 in a granular medium. The structural component represents nonrandom structural influences, including macropores, and is arithmetically defined as the difference between the textural porosity and the total porosity.

The texture of the medium relates in a general but complex way to the pore-size distribution, as large particles may give rise to large pores between them, and small particles may give rise to small pores, or to additional large pores if their clay mineralogy causes aggregation. Additionally, the structure of the medium, especially the pervasiveness of features like aggregation, shrinkage cracks, and wormholes, substantially influences hydraulic properties.

Measurement of porosity

Porosity is the volume of pores divided by the total soil volume, which can be calculated using the difference between total sample volume and total particle volume. Usually this is not done directly but with measurements of bulk density ρ_b and particle density ρ_p . From their definitions as total particle mass divided by total volume (ρ_b) or by particle volume (ρ_p), the ratio ρ_b/ρ_p is the complement of ϕ , so that

$$\phi = 1 - \frac{\rho_b}{\rho_p} \quad (1)$$

For a soil of unknown ρ_p , a value of 2.65 g/cm³ (corresponding to quartz) is frequently used. Often the main source of error arises from uncertainty in the total soil volume used to determine ρ_b . If a minimally disturbed sample of soil of known shape (e.g. cylindrical) can be obtained, its volume can be calculated from its dimensions. Significant error can result from irregularities in the actual shape and from compaction during the sampling process. Alternatively, the measured volume can be that of the excavation from which a bulk soil sample has been extracted. Various methods such as the balloon and sand-fill methods, as well as by filling the lined hole with a known liquid such as water, can indicate the total volume.

Another way to determine porosity is from the volume of water contained in a saturated sample of known volume. The mass of saturated material less the oven-dry mass of the solids, divided by the density of water, gives the volume of water. Dividing this volume by the original sample volume gives the porosity. An analogous method is to determine the volume of gas in the pore space of a completely dry sample. Sampling and drying of the soil must be conducted in a way that does not compress the soil or otherwise alter its porosity. A pycnometer can measure the air volume in the pore space. It works with a gas-tight chamber enclosing the sample so that the internal gas-occupied volume can be perturbed by a known amount while the gas pressure is measured. Boyle's law indicates the total gas volume from the change in pressure resulting from the volume change. This total gas volume minus the volume of air-filled portions of the apparatus apart from the soil yields the total pore volume to be divided by the sample volume.

Tomographic imaging or the older technology of thin sections can produce a visualization from which porosity can be calculated. With a three-dimensional image the volume of pore space divided by total volume gives the volumetric porosity. With a two-dimensional image an analogous procedure can be followed using areas, giving the areal porosity over the imaged plane, or using segment lengths along a line through the sample to yield a linear porosity. If the medium is isotropic, these would numerically equal the volumetric porosity. Imaging tends to underestimate the total porosity, as the smallest pores cannot be resolved.

Pores and their spatial characterization

The nature of a pore

Because soil does not contain discrete objects with obvious boundaries that could be called individual pores, the precise delineation of a pore requires artificial, subjectively established distinctions. This contrasts with soil primary particles, which are easily defined, being discrete material objects with obvious boundaries. The criterion selected to partition pore space into individual pores is often not explicitly stated when pores or their sizes are discussed. Because of this inherent arbitrariness, some scientists argue that the concepts of pore and pore size should be avoided. Much valuable theory of the behavior of the soil-water-air system, however, has been built on these concepts, defined using criteria that are accepted widely, if not universally.

Pores can also be classified according to their origin, function, or other attributes. A textural/structural distinction is possible, as it is for porosity. Inter-granular pores are the major portion of soil textural porosity, as discussed above. Intra-granular or dead-end pores (if not entirely enclosed within solid) might empty or fill with water, but without contributing as directly to fluid movement through the medium. Intra-aggregate pores may be essentially equivalent to inter-granular pores within an aggregate. Inter-aggregate pores, including shrinkage cracks, are common types of macropores, in addition to biogenic pores, for example the channels left by decayed roots and tunnels made by burrowing animals.

Pore-size characterizations rely heavily on a conventional idealization of pores as being cylindrically symmetric, which is far from true, given the irregular shapes of grains and pores in real soils. For realistic pore shapes the effective width varies along the axis of flow. Relatively wide portions are often called pore *bodies* and the relatively narrow portions that separate the pore bodies called

pore *necks*. Other anatomical metaphors are sometimes used, the wide part of a pore being the “belly” or “waist”, and the constrictive part being the “throat”. In a medium dominated by textural pore space, like a sand, pore bodies are inter-granular spaces of dimensions typically slightly less than those of the adjacent particles. At another extreme, a long wormhole, especially if its diameter is essentially uniform along its length, might be considered a single pore. The boundaries of such an elongated pore are of three types: (1) interface with solid, (2) constriction—a plane through the locally narrowest portion of pore space, or (3) interface with another pore (e.g. a crack or wormhole) or a hydraulically distinct region of space (e.g. the land surface).

Pore sizes are often specified by an effective radius, r , of the pore body or neck. Alternative indicators of size include the cross-sectional area or the volume of a pore, and the hydraulic radius, defined as the ratio of the cross-sectional area to circumference, or of pore volume to specific surface.

Methods for measuring or estimating pore size fall mainly into two categories, those based on imaging and those based on hydraulic behavior. In the usual case where it is more important to characterize a medium than an individual pore, these are applied to measure many pores so as to obtain a pore-size distribution, as discussed further in the next section.

Measurement and representation of pore-size distribution

The pore-size distribution is the relative abundance of each pore size in a representative volume of soil. It can be represented with a function $f(r)$, which has a value proportional to the combined volume of all pores whose effective radius is within an infinitesimal range centered on r . Fig. 2 shows examples. Like porosity, $f(r)$ may be taken to comprise textural and structural components.

Based on measured geometry

The most obvious and straightforward measurements of pore size are with geometric analysis of images. X-ray computed tomography (CT) enables 3D imaging of the interior features within a soil. Access to CT scanners has increased dramatically since the 1990s (Vogel et al., 2022), and this 3D imaging technique has largely replaced the pore structural analysis of 2D thin sections.

From two- or three-dimensional images, bodies and necks can be measured by image analysis (Lindquist et al., 2000). In three dimensions, an often-used technique is to determine the maximum inscribed sphere in each pore, i.e. the diameter of the largest sphere that fits inside the pore (Hildebrand and Rügsegger, 1997). Image-based techniques, however, come with a strong trade-off between sample size and resolution; the small samples needed for high resolution do not capture large macropores. This trade-off also affects topological measures such as pore connectivity. The effect can be minimized by combining different sample sizes (Lucas et al., 2021; Vogel et al., 2010). In two-dimensional image analysis, the plane of the image does not always intersect the widest parts of the pore bodies and necks, so mathematical correction techniques are necessary to estimate unbiased pore body and neck sizes. In addition, information about topological features like pore connectivity is lost.

Three-dimensional analysis of geometry is also possible with impregnation techniques. In these, the soil pore space is filled with a resin or other liquid that solidifies. After solidification, the medium is broken up and individual blobs of solid resin, actually casts of the pores, are analyzed as particles. Incremental sectioning and imaging of the 3D impregnated block can also be used to reconstruct the 3D pore space, albeit with considerable effort.

Fig. 2 Pore-size distributions of a sandy clay loam and a silty clay soil, measured by mercury intrusion. Adapted from Calderón MJ, Real M, Cabrera A, Koskinen WC, Cornejo J, and Hermosín MC (2015) Influence of olive oil mill waste amendment on fate of oxyfluorfen in southern Spain soils. *CLEAN – Soil, Air, Water* 43(7): 1107–1113. doi:10.1002/clen.201400560.

Based on hydraulics

More commonly used than imaging methods are those based on effective capillary size inferred from measured hydraulic properties. These indirectly measure pore sizes from data concerning fluid behavior in the unsaturated medium, usually the emptying or filling of pores during soil drying or wetting (Fig. 3). Most commonly this is done using a water retention curve $\theta(\psi)$, where θ is the volumetric water content and ψ is the matric pressure. The relation between the measured data and specific quantifications relies on a process-based interpretation of measurement techniques.

Because large pores fill or empty at ψ near 0, a medium that has many large pores will have a retention curve that drops rapidly to low θ as ψ decreases from 0. Conversely, one with very fine pores will retain much water even at highly negative ψ , thus having a retention curve with more gradual changes in slope. Quantified using capillary theory, the effective pore radius corresponds to the ψ at which a pore empties or fills according to

$$r = \frac{-2\sigma \cos \alpha}{\psi} \quad (2)$$

where σ is the surface tension and α is the contact angle. This formula can convert a measured $\theta(\psi)$ into an equivalent $\theta(r)$ curve. This curve is actually a cumulative pore-size distribution; the water content on a drying $\theta(r)$ indicates the combined volume of all pores with neck radius less than r . Applying the fundamental theorem of calculus, the pore-size distribution is simply the derivative. This function is the basic equivalent-capillary representation of pore-size distribution.

$$f(r) = \frac{d\theta}{dr} \quad (3)$$

This method has a serious limitation in media subject to pore blockage during emptying or filling (Mualem and Dagan, 1975). On a drying curve, for example, there can be pores that remain filled even when ψ is at a value that should have them empty according to Eq. (2), if they are completely surrounded by empty pores such that there is no path to accept water exiting from pores that are isolated within. The consequence is that the abundance of pores of larger size will be underestimated when inferred from the drying water retention curve. The reverse holds true for a wetting curve.

Fig. 3 Dynamics of a Haines jump. Adapted from Miller EE and Miller RD (1956) Physical theory for capillary flow phenomena. *Journal of Applied Physics* 27(4): 324–332.

Mercury porosimetry is analogous to the water-retention based method, but uses air instead of water as the wetting fluid and mercury instead of air as the nonwetting fluid. Mercury is forced into the pores of dry soil incrementally, and the relation between mercury content and mercury pressure recorded. Applying Eq. (2) with the appropriate values of surface tension and contact angle for mercury gives the estimated pore-size distribution.

The effective radius can be directly related to the radius of curvature of the air-water interface at the occurrence of Haines jumps, a basic phenomenon of capillary hysteresis, illustrated in Fig. 3. The pore necks, which control the value of ψ at which pores empty, are smaller than the pore bodies, which control the ψ at which pores fill. As the medium dries and ψ decreases, water retreats gradually as the air-water interface becomes more curved. At the narrowest part of the pore neck, this interface can no longer increase curvature by gradual amounts while satisfying the capillary relation (2), so it retreats suddenly to narrower channels elsewhere. An analogous phenomenon occurs during wetting, when the decreasing interface curvature cannot be supported by the radius of the pore at its maximum width. The volume that empties and fills in this way is essentially that of an individual pore, though not all pore space is subject to Haines jumps—water remains in crevices and in films (not shown in Fig. 3) coating solid surfaces. Various models and theories treat this space in different ways. By the definition above it is part of a pore in addition to the volume affected by the Haines jump.

The Haines jump concept can be used to give separate size distributions for pore necks and pore bodies. Applying Eq. (3) to data from a drying retention curve indicates neck radii; applied to wetting curve data, it indicates body radii.

Comparison of methods

The different measurement techniques of soil pore-size distribution do not give exactly the same results, as they are based on different concepts and biased by different characteristics of soil. Fig. 4 shows a diagram noting the ranges of validity of selected

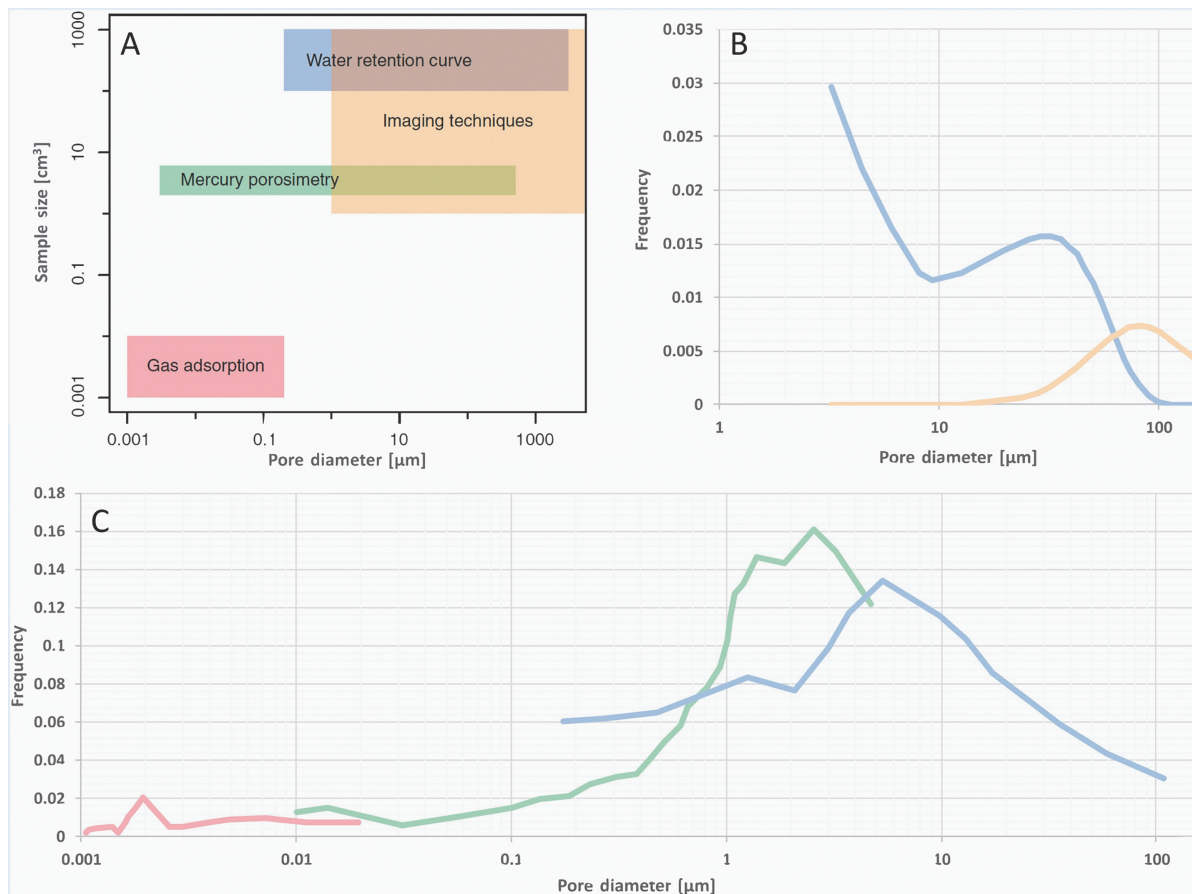

Fig. 4 Pore-size distributions obtained by different methods. (A) Comparison of the range of accessible sample size and pore size for the different methods. Both axes are represented with a logarithmic scale. (B) Pore-size distribution of a loamy sand soil derived from water retention (measured by the evaporation method) (blue) and computed microtomography (light brown). (C) Pore-size distribution of loess soil derived by water retention, mercury intrusion porosimetry, and gas adsorption. Curve colors in (B) and (C) correspond to those of the labeled rectangles in (A). (B) Adapted from Geistlinger H and Leuther F (2018) Evaporation study for real soils based on HYPROP hydraulic functions and micro-CT-measured pore-size distribution. *Vadose Zone Journal* 17(1): 180041, doi:10.2136/vzj2018.02.0041. (C) Adapted from Hajnos M, Lipiec J, Świeboda R, Sokołowska Z, and Witkowska-Walczak B (2006) Complete characterization of pore-size distribution of tilled and orchard soil using water retention curve, mercury porosimetry, nitrogen adsorption, and water desorption methods. *Geoderma* 135: 307–314. doi:10.1016/j.geoderma.2006.01.010.

methods, and examples of substantially different results from different methods. Results often differ even where the methods overlap in pore-size range. Different methods are affected differently by unintended influences. For methods based on retention or intrusion, emptying and filling depend on more than capillarity; contact angles, for example, are dynamic and are unlikely to equal handbook values, so they may deviate significantly for water and for mercury. The swelling of clays can be a major influence on a water retention curve, though negligible for retention measured with mercury. Imaging techniques are subject to some entirely different influences such as resolution and image quality. Another influence is the sample size typically used for the specific method (Fig. 4A). Macropores, for example, may be representatively captured in large soil samples used in imaging, but are not captured in the relatively small sample sizes used for gas adsorption. In Fig. 4B, the pore size distribution derived from a water retention curve (blue) indicates a greater abundance of smaller pores than that based on CT measurements (light brown), in part because the drying curve used for this purpose gives a measure of pore neck rather than body sizes, and also because it relies on dynamic accessibility of pores to the incoming fluid. In addition, for distributions measured by hydraulic means such as water retention, caution is needed in interpretation at the extremes, as the driest and wettest portions of a retention curve are determined by factors other than capillarity. In soil environmental applications, the water retention method is most often used, in large part because these data are more commonly available. One can also expect a water-based method to give better results for a water-based application such as predicting hydraulic conductivity.

Typical features of a pore-size distribution

Fig. 5 illustrates how $f(r)$ can be apportioned into different classifications of pore type. Corresponding graphs of the cumulative size distribution can be used equivalently.

Often a specific functional form or other representational model of pore-size distribution is useful. A normal or lognormal distribution can be fit to the data, for example. Self-similar or fractal forms of the distribution function also can be used, giving a power-law form of the cumulative pore-size distribution. If the actual distribution is unimodal, these functional forms can work well by themselves. Structural features, however, may give the soil a bimodal pore-size distribution, leading to several distinctive effects on water flow. Some soils may have three or more peaks. Multimodal distributions can be represented by superpositions of the normal or lognormal forms.

The minimum conceivable size of a soil pore, given that it must contain at least a few molecules, is about 1 nm. Fluid behavior in such small pores would be dominated by interaction with the solid material, and not likely describable by capillary laws or even standard thermodynamics. The smallest pores measured by water retention or mercury intrusion are typically 50 or 100 times larger than this, though with greater cost and effort, greater magnitudes of pressure and hence smaller measured r can be achieved. Because r relates inversely to ψ , the dry portion of the $\theta(r)$ retention curve, and correspondingly of $f(r)$, is confined to a small region near $r = 0$, where the apparent number of pores becomes large. In an extreme case in which θ is held to remain artificially finite as ψ goes to negative infinity, at $r = 0$ $f(r)$ approaches infinite height in the form of a delta function.

At either pore size extreme, where capillary phenomena lose dominance, Eq. (2) no longer applies, though it still can give r values corresponding to ψ . These values are purely artificial in character, having no relation to the actual radii of capillaries, though they may be useful for translating one property to another (discussed below). At the dry extreme, water is not likely to be in filled pores but rather in thin films that coat particles of soil.

Peaks in $f(r)$ are apparent if they fall within the r -measurement range of the method (see Fig. 4C). Such a peak corresponds to an inflection point in $\theta(r)$. The inverse relation of r to ψ means that $\theta(\psi)$ is more likely to show an inflection point than $\theta(r)$; if $\theta(r)$ has an inflection point, then $\theta(\psi)$ is mathematically required to have an inflection point, but the converse is not true. The case of a retention curve that shows a wide range of slopes (typically with an inflection point within the measured range and a distinct initial-Haines-jump or air-entry effect at a nonzero value of ψ) will have a defined peak in the pore-size distribution if the middle portion

Fig. 5 Pore-size distribution with subregions distinguished for different types of pores on the basis of pore body and neck radii and drying/wetting history. Adapted from Lucas, M., Vetterlein, D., Vogel, H.-J., & Schlüter, S. (2021). Revealing pore connectivity across scales and resolutions with X-ray CT. *European Journal of Soil Science* 72(2): 546–560. doi:10.1111/ejss.12961.

of the retention curve has a slope that differs markedly from that of the two end segments. This is frequently true for monodisperse media and for repacked samples, in which pores larger than a certain r have been destroyed. For many soils, perhaps most, $f(r)$ does not have a peak except at $r = 0$, or so close to 0 that it cannot be measured. This is especially likely for media that are macroporous, polydisperse, or that show an air-entry effect with ψ very close to 0. Retention curves of this type may be best represented by a fractal or power-law model. Lognormal models or other representations that have a defined peak can often still be applied but with the peak outside the measurable range. Predictive models of hydraulic properties such as hysteresis and conductivity may be unaffected by the lack of a measurable peak even if they are applied using a pore-size distribution that resembles some form of normal distribution.

Relation to soil properties and processes

A major importance of a soil's porosity and pore-size distribution is that they relate to other soil properties in a complex and useful way; they can be interpreted to reveal important insights and used to predict other properties of soils.

Effects of pore-space characteristics on other soil processes

One obvious significance of porosity is that it is an upper limit of volumetric water content. It is similarly essential to the definition of degree of saturation, θ divided by porosity. Another significance is that within the pore space, the complement to θ is gas content. That is, volumetric gas content equals the difference between θ and porosity.

The magnitude of porosity roughly indicates complexity of structure, being greater for greater complexity, as noted above for aggregated soil. Additionally, the spatial variability of porosity is important, and also correlates with greater structural complexity. For pore-size distribution the most obvious connection is the relation to the water retention curve as elaborated above. In addition, if both wetting and drying water retention curves are known, their difference reveals the extent of hysteresis and thus gives information about both pore-neck and pore-body distributions. Conversely, if both neck and body sizes are known from image analysis, the magnitude of soil-water hysteresis can be estimated.

Because pores are fluid conduits, their size distribution is useful for predicting hydraulic conductivity K . The usual assumption applied is that the pores act hydraulically as if they are cylinders of the same effective radius, providing a simple geometry for applying hydrodynamic formulas (e.g. Childs and Collis-George, 1950). Popular models include those of Mualem (1976) and Burdine (1953), which have been analytically combined with widely used empirical formulas for retention curves. Gas and other types of fluid transport can be treated similarly.

For solute transport, the pore-size distribution affects solute convection similarly to hydraulic conductivity. Additionally, it affects solute dispersion, which is expected to be greater for a broader pore-size distribution. The pore-size distribution affects the sorption of solutes in a complex way: smaller pores are associated with longer residence times but most solutes may bypass them and pass quickly through the large pores with minimal opportunity to react. Interchange between fast- and slow-transporting portions of the pore space is a vital and much-investigated aspect of solute transport in soils. Smaller pores are associated with greater relative surface area, and thus may correlate with a greater capacity for sorption.

For particle transport, many aspects are essentially the same as for K and solute transport. Additionally, the phenomenon of straining depends critically on the proportion of pores smaller than a given particle size. This is the dominant factor in some particle-transport applications.

The large-radius portion of the pore-size distribution may be indicative of macropore space and thus relate to the processes of macropore flow and aeration. In addition, increased volume of macropores may be linked to their mode of origin (e.g., earthworm channels or root holes). It is at the same time an important habitat consideration for soil fauna, and may also be important for root growth in soil of high mechanical impedance. Similarly, at the other extreme, pores in the tens of microns size range may represent optimal microbial habitats, leading to high enzyme activity (Kravchenko et al., 2019).

The pore-size distribution is a critical aspect of the overall structure of a soil, the spatial arrangement of pores and solids. More about soil structure can be found in the soil structure article. To link pore structure to its functions, however, the pore space needs to be described by more than just its pore-size distribution and porosity. Additional important inputs include various topological characteristics of pore-space images, such as tortuosity or anisotropy. A particular concept of interest is the Minkowski functionals. In three dimensions these geometric measures include pore volume, surface area, and mean curvature, as well as connectivity described by the Euler number. The determination of the Minkowski functionals as a function of pore size can be used to describe the pore space fully by a small set of parameters and thus link pore structure to physical processes (Vogel et al., 2010).

Pore dynamics

Natural and human-induced soil processes create and destroy pores, and induce changes in their size and other attributes. Table 1 lists some of the common effects on pore-size distribution caused by routine processes. In general, if the soil is compacted by uniform stress, such as a weight imposed at the land surface, it normally loses large pores and gains small pores. Disturbance from irregular stresses, as during digging or repacking, has a variety of effects on pore size, often with the effect of a net decrease in the number of large pores and an increase in the number of small pores. Though small inter-granular pores are seldom closed

Table 1 Possible effects of routine soil processes on pore-size distribution.

Soil process	Effect	Further reference
Shrinkage	Enlarged macropores New macropores created Within an aggregate, intra-aggregate pores decrease in size, or increase in size if clay particles shrink	Swelling and shrinking Freezing and thawing processes at field scale
Swelling or frost-heaving	Decrease in the size of macropores Closed macropores Within an aggregate, intra-aggregate pores increase in size, or decrease in size if clay particles expand	Freezing and thawing cycles
Mechanical compression	Decrease in size of macropores Closed macropores Aggregates break up, reducing the number of intra-aggregate pores, thereby reducing the proportion of the smallest pores	Compaction
Disturbance from digging or plowing	Existing macropores destroyed Interclod macropores created Aggregates break up, reducing the number of intra-aggregate pores, also the fraction of the pore space represented by the smallest pores	Tilth
Biological activity	New macropores created, often with concurrent reduction of smaller pores, e.g., by compression of soil surrounding a growing root Enlarged macropores, as by ongoing traffic of ants or burrowing mammals Constricted or obstructed pores, e.g., through growth of microorganisms Increased aggregation, promoting the creation of inter-aggregate macropores, and possibly smaller inter-granular pores within aggregates	Root physical constraints Bioturbation; Siul Ruiz Reinforcement by roots
Chemical activity	Constricted or obstructed pores through formation of precipitates Enlarged pores through dissolution of precipitates Increased or decreased interparticle cohesion, with complex effects on pore size and structure	Salinity, Physical effects

completely, some processes can close macropores, in effect destroying them. Several types of processes can create pores. Roots, for example, can create a dense system of biopores whose tubular form can connect over long distances.

Conclusions

The characterization of pore space is a vital and fruitful aspect of soil investigation. Physical, chemical, and biological influences acting on the liquid, solid and gas constituents of the soil determine the form and development of pores, whose character in turn profoundly influences the nature and behavior of the soil. It relates to all major soil functions, including water storage and flow, carbon storage and organic matter turnover, as well as plant growth and biodiversity.

Soil porosity is fairly well standardized in definition and measurement techniques. Pore size, however, is not obvious how to define, and consequently has no unique standard of measurement. It is difficult to consider pores on an individual basis without talking about interactions with water and other materials. Yet pore-size concepts are central to topics like macropores, aggregation, fractures, soil matrix, and solute mobility. Pore size plays a key role in various proposed means of quantifying soil structure. It also has a major practical role in the prediction of hydraulic properties. New pore size concepts, measurement techniques, and relations to a great diversity of soil properties and processes are likely to remain a major emphasis in the study of soil.

Abstract

Soil physical and other properties are usually studied in the laboratory or field to parameterize continuum-scale models. Such measurements may result in numerous inaccuracies or are based on false assumptions. With recent development in soil structure imaging and characterization techniques a detailed 3D information on the inner structure of a soil sample can be acquired. With such an input data pore-scale modelling approach is indispensable in simulating the processes taking part within the pore (or solid) space. Modelling approach allows to obtain such properties on any scale required and upscale them to continuum-scale. In this chapter we briefly describe theoretical and practical basics to use pore-scale modelling in soil science applications limiting our focus to flow and transport properties.

Key points

- Pore-scale modelling is an emerging technique that is capable of simulating soil processes on different scales where they are inaccessible by direct measurements
- With a variety of available free and commercial tools any soil scientists may incorporate pore-scale modelling into research
- Continuum-scale models will benefit from parameterization from or coupling with pore-scale models

Introduction

Soil physical properties such as hydraulic conductance (Ksat chapter reference), water retention curve and relative permeabilities are highly interconnected to all other soil functions, as they describe water and solute transport within soil. This is hard to overestimate the importance of these properties, as they affect moisture and nutrients availability to plants, (micro)organisms — all, in turn, determinate soil fertility. As such, physical soil properties are the fundamental building blocks of all major models aimed at describing soil processes, e. g., those including the Darcy and Richardson-Richards equations. What usually lacks the necessary attention is that all such properties are at the continuum-scale — this means they represent some “averaged” value attributed to a volume of soil. This averaging step, or homogenization (Fig. 1), is based on pore-scale information such as pressure and flow velocities fields. This is the information that can be obtained with the help of pore-scale modelling approaches.

Pore-scale modelling operates at one level below the continuum-scale and explicitly describes fluid interfaces and velocities. Unlike the continuum-scale, which does not know anything about the soil except for the homogenized property, pore-scale describes the so-called structure-property relationship — how fluids (solutes and air) interact with soil solids (e. g., mineral, clay and organic components and their mixtures). The interaction parameters, such as interfacial tensions, velocity slip or contact angles, are themselves homogenized values that can be measured either experimentally (but this is problematic for some properties) or modelled with the help of molecular dynamics (MD). The MD simulations describe the motion and interaction of individual molecules and, due to computational expense, allow only a limited modelling domain — e. g., a single nano-pore or fluid droplet on the substrate. A density-function theory (DFT), if properly parameterized and combined with MD (Vaganova et al., 2022), is another efficient way to assess pore-scale characteristics. Hence, pore-scale modelling is sandwiched in-between MD or DFT at the molecular scale and the classical continuum-scale and a part of the general multi-scale physical framework to describe flow and transport processes within porous media.

In soil physics and hydrology pore-scale simulations provide a novel perspective on understanding numerous aspects of the flow and allow the fixing of numerous flaws of the experimental techniques:

- 1) Unsaturated hydraulic conductances (two-phase flow soil experiments) are hard to measure experimentally. This has resulted in the total domination of unphysical statistical methods, such as pedotransfer functions;

Fig. 1 Homogenization and continuum-scale flow modelling in soils based on the pore-scale simulations – a general scheme.

- 2) Measurement errors due to technological drawbacks (e. g., [Diamond, 2000](#)), such as tool inaccuracies or faulty physical assumptions;
- 3) Changes to the physical properties of samples under laboratory measurements by cracking, self-filtration and other processes;
- 4) Distortions by boundary effects due to coring or sampling;
- 5) Inability to account for dynamic structure influences on transport properties;
- 6) Failure to assess tensorial ([Guibert et al., 2016](#); [Gerke et al., 2019](#)) or even directional properties (e. g., soil cores provide quasi-1D flow properties);
- 7) Field or laboratory measurements provide no information if the studied soil is representative elemental volume (REV) ([Gerke and Karsanina, 2021](#)), as structural information (pore structure or flow field) is needed to assess representativeness.

While pore-scale modelling in soil science is still in early development, the potential of this approach to uncover important aspects of flow physics in soils is without doubt. Moreover, pore-scale flow and transport models can be coupled to other critical processes — mechanical ([Hallett and Newson, 2005](#); [Barbosa et al., 2022a](#)) or biological ([Schnepf et al., 2022](#)) models, to name just a few possible directions. The aim of this contribution is to provide a brief description of pore-scale modelling of flow and transport in general (with practical links to existing codebases) and to discuss why such techniques will inevitably become main-stream for solving various problems in soil physics and beyond.

Input data and pore space characterization

The critical input data for pore-scale models is the 3D geometry of the pore space of the studied soil sample (reference to soil structure chapter). Such information usually comes from X-ray tomography (XCT) imaging ([Abrosimov et al., 2021a](#)) (reference to X-ray tomography chapter) that received widespread adoption for characterizing soil structure. The fundamental problem of almost any imaging method is the ratio of the field-of-view to imaging resolution — the larger the soil sample, the lower the resolution. Consequently, covering hierarchical soil structural features at all interesting scales requires multi-scale imaging with sub-sampling ([Karsanina et al., 2018](#); [Lucas et al., 2021](#)). The leap in imaging techniques development and availability of the XCT devices is facilitating progress in pore-scale modelling.

Unfortunately, XCT imaging alone is either not enough or not applicable in each study situation. This problem is particularly pronounced for nano-scale imaging and owing to some organic matter invisibility on XCT — both can be mitigated with the help of focused ion beam — scanning electron microscopy (FIB-SEM) imaging ([Gerke and Karsanina, 2021](#)). In addition, thin-sections are not only useful to discern different solid phases, including organic matter and mineral crystal orientation, they also provide means of building 2D maps of microbial activity and mineral composition ([Raynaud and Nunan, 2014](#)), these later can be extended over 3D soil structural images.

The 2D nature of some imaging techniques fails to provide meaningful input data for pore-scale modelling methods due to their inherent need for 3D information. Stochastic reconstruction techniques allow re-creation of 3D structure based on limited 2D or 3D information. Different approaches, such as process-based methods (Barbosa et al., 2022b), multiple-point statistics and simulated annealing based algorithms and their hybrids, may provide an effective solution for different structures such as sandy soils, clayey soils or aggregates. The usage of stochastic reconstructions to produce soil images has been attempted in a limited number of studies (Zhang et al., 2005; Karsanina et al., 2015), but is expected to grow in the near future, especially because of the need to fuse multi-scale images into a single 3D digital structural model (Karsanina et al., 2018).

The majority of 3D images obtained by any approach, as mentioned above, will represent gray-scale image with voxel color representing X-ray attenuation or the intensity of electron back-scattering. To separate pore and solid voxels one needs to apply a segmentation procedure, or binarization. In our opinion, the soil science community still have not produced a superior specific segmentation procedure; moreover, automatic binarization techniques usually result in poor image processing (Abrosimov et al., 2021b). Among existing techniques, converging active contours (Sheppard et al., 2004), indicator kriging (Oh and Lindquist, 1999) and region growth (Hashemi et al., 2014) provide a good trade-off between quality and computational expense. If the original image is too noisy, an open-source non-local means filter (Bruns et al., 2017) can be a helpful pre-segmentation step. Note that due to the resolution limit, any segmentation of the XCT image by default introduces errors — see a discussion of this effect and a possible solution with the help of the deep supervised learning on physically modelled data in Lavrukhin et al. (2021).

After the 3D image of porous space is obtained, it can serve (together with any additional information) as input data for pore-scale modelling. However, one additional step in pore characterization is needed for so-called pore-network modelling approach. The idea is to simplify the geometry of the porous space by representing it with the help of pore and throat elements with a limited variety of shapes while conserving the topology. The classical approach to represent pore shapes is the circle-triangle-square or CTS approach (Valvatne and Blunt, 2004) was critiqued for its inability to represent non-convex shapes. It was later shown that one can remove the simplification of the shapes completely with the help of direct solutions and machine learning (Miao et al., 2017). The problem of topology conservation was recently solved (Zubov et al., 2022), as it was shown that all popular extraction methods fail in preserving pore-network's Euler numbers (Gerke et al., 2020). At the time of writing the dominant state-of-the-art extraction approaches include watershed-based (Rabbani et al., 2014; Gostick et al., 2016), median axis-based, maximal inscribed balls (Dong and Blunt, 2009) algorithms, and their hybrids (Gerke et al., 2020). In addition to the ability to effectively simulate single and multi-phase flow, the extraction of the pore-network models also allows morphological analysis such as pore and throat size distributions, pore shapes and related properties. The example of the 3D image of the soil pore space and of the extracted pore-network model is shown in Fig. 2 in the form of so-called ball-and-stick diagram (note that this representation is chosen due to visibility, pores are not spheres while throats are not cylinders).

For multi-flow simulation in addition to 3D pore geometry the parameters of the fluid-fluid and fluid-solid interactions are needed. These are usually supported in the form of the contact angles that are linked to interfacial tensions or free energy potentials. The value of static and dynamic (during fluids movements) contact angles depend on a number of parameters such as chemical constitution of the fluid and solids, roughness of solid walls and the history of the interaction between solids and fluids. Static contact angles are either measured in the laboratory on prepared surfaces (link to contact angle chapter) or can be measured in situ based on XCT tomography. Dynamic angles are obtained either through direct pore-scale modelling or recalculated from static counterparts using empirical models. Both static and dynamic contact angles of confined fluids in nanopores can be also modelled using MD or Hydrodynamical DFT approaches.

Fig. 2 The results of the pore-network extraction procedure — the PNM is extracted from the 3D pore space image (left) and is usually represented with the help of the ball-and-stick diagram (middle). Note that this does not mean that pores are spherical and throats are cylindrical. To visualize the correspondence of the PNM model to the original pore space geometry we also show PNM embedded into the solid phase of the soil sample studied (right).

Numerical methods

The flow of fluid(s) on the pore-scale is classically described by a Navier-Stokes equation:

$$\begin{cases} \frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla) \mathbf{v} - \frac{\mu}{\rho} \Delta \mathbf{v} + \frac{\nabla p}{\rho} = 0 \\ \operatorname{div} \mathbf{v} = 0 \end{cases}, \quad (1)$$

where $\mathbf{v} = (v_x, v_y, v_z)$ is velocity field, μ is fluid viscosity, ρ is fluid density, and p is pressure field. This equation can describe the flow in a wide variety of velocity magnitudes starting from the very slow to high-velocity turbulent regimes. It is generally assumed that porous media flow, including within soils, happens with very low velocities (as characterized by so-called Reynolds number, Re , that should be less than 1 for Darcy equation to hold after homogenization, $Re = \frac{\rho u l}{\mu}$, where u is the absolute flow velocity and l is the characteristic length of pore or channel). In the case of $Re < 1$, the flow happens in creeping or Stokes regime and can be described by a simplified version of Navier-Stokes equation (with eliminated inertia term) that is called Stokes equation:

$$\begin{cases} \mu \Delta \mathbf{v} - \nabla p = 0 \\ \operatorname{div} \mathbf{v} = 0 \end{cases}. \quad (2)$$

Unlike Eq. (1), Eq. (2) does not contain time — this form of the equation is used to show that in this case we are interested only in single-phase properties, one needs to solve a stationary problem and, thus, time can be excluded. The case where the transient problem is of interest, Stokes equation can include the time variable similarly to Eq. (1). Both Eqs. (1) and (2) can be solved numerically if some boundary conditions, e. g., pressure differences on the sides of the modelling domain, are known; and the spatial discretization of the modelling domain is performed. The latter is usually performed with cubical cells, as they are naturally arising from X-ray computed tomography images. However, depending on the numerical method utilized some other type of computation mesh such as tetrahedral or unstructured meshes could be preferred. This, however, add another complexity level on top of image processing, as one needs to create a mesh based on segmented pore space 3D image first.

Eqs. (1) and (2) are written for single-phase, or saturated flow. It is possible to modify these equations to include any number of fluids in case they are immiscible (by adding subscripts for all different fluids considered). However, to close the system we also need to describe the interaction between fluids and solid phases, as well as between the fluids themselves. Here, the choice of the model depends on the numerical method that is chosen and the boundary can be either exact or diffuse. In other words, we solve the same flow problem as for single-phase flow, but for each fluid involved plus interaction between fluids and with the solid phase. This results in a much more computational intensity needed for simulating multi-phase flow.

There are plenty of diverse numerical method to solve single- and multi-phase flow equations at the pore-scale: different classes of finite-difference (FDM), finite-element (FEM), finite-volume (FVM) methods, lattice-Boltzmann methods (LBM) and smooth-particle hydrodynamics (SPH). Multi-phase flows require the treatment of the phase boundary tracking, i.e. volume-of-fluid (VOF) approach or a phase field methods. They differ not only in terms of the solution of Eqs. (1) and (2), but also in terms of the description of the interactions between solid and fluid phases. For example, VOF method allows exact interface tracking, but this feature is computationally heavy and may produce artifacts for some specific pore geometries. The phase-field methods operate on the diffuse-boundary, e.g., as described by the Cahn-Hilliard potential model. Although in the case of the diffuse boundary there is no abrupt interface between the fluids, this approach allows more physical description of the interactions based on free energy (that can be utilized to parameterize contact angles). The choice of the method to use in each case is non-trivial and depends on the aims of the numerical study, as each approach may have its significant advantages and pitfalls. The authors tend to gravitate in the direction of phase-field models in case of direct multi-phase flow simulations within soils. The most popular LBM approach is easy to implement within the code and to parallelize, but the physical model behind, especially for multi-phase flow is questionable (despite a widespread delusion that LBM generalized to Navier-Stokes equations).

The computational efficiency of different methods is hard to be compared as it depends on numerous aspects of the numerical code, including the solution method, the architecture of computational resources (e. g., potential usage of hybrid CPU + GPU), the choice of the libraries or compilers and explicit or implicit numerical schemes. As a rule of thumb the more computationally expensive the method is, the more accurate the solution is. The majority of existing codes or software utilize explicit schemes due to the ease of implementation and parallelization (which is usually linear to the number of cores used). The design and coding of implicit numerical schemes is much more involved, but it is expected to start dominating direct pore-scale simulations in the future. The benefit of implicit schemes is that such schemes can solve stationary equations with a few iterations (Stokes flow) or allow significantly larger time steps that don't depend on the temporal discretization (unlike LBM or explicit methods). The drawback of such schemes is their complexity and a need to solve large scale systems of linear equations and complexity in their parallelization. However, with the usage of asymptotically optimal iterative linear solvers (i.e. multigrid methods) one can expect optimal performance that is proportional only to the size of the domain discretization.

Compared to direct pore-scale models which are based on Eqs. (1) and (2) solutions, pore-network models are orders of magnitude more computationally efficient. We argue that PNMs are actually the only available technology to perform practical pore-scale simulations of large volumes of soil material, as direct models require high-performance resources to describe rather small volumes (usually limited to 1000^3 voxels depending on the imaging resolution, porosity and number of phases among other factors). Pore-network simulators significantly reduce computation times by solving the flow on the graph with hydraulic

conductances for saturated and unsaturated flow that are already prescribed on each pore-throat-pore element based on simplified geometry (Tuller et al., 1999; Patzek and Kristensen, 2001) or based on neural network prediction (Miao et al., 2017). Therefore the solution for saturated hydraulic conductance takes a mere second, while two-phase (air-water) simulations may require from minutes to hours on a single CPU compared with days to weeks on a multi-CPU cluster for direct models. The significant variation for computational times for unsaturated flow is due to the complexity of pore-network used. Roughly speaking, PNM can be divided into two classes — quasi-static and dynamic models. The former assumes that viscous forces are negligible, i.e., flow occurs slowly and can be described within some capillary pressure steps — the displacement of one fluid with the other depends only on local menisci curvature. The latter takes viscous forces into account and describes some dynamic effects due to flow velocity (hence the name). The idea behind the first class of models is that all major unsaturated flow processes are rather slow and capillarity is the dominating force. Whether this is true for all soils during gravitational water flow is an open question, as soils have a wide variety of pore sizes. Some pressure boundary conditions, for example, water table above the soil, or larger pores may reduce the importance of capillary forces and make viscous forces dominant. In this case dynamic pore-network models are necessary to describe flow (Joekar-Niasar and Hassanizadeh, 2012). The ability to account for viscous forces does not come in for free — one needs to solve much more involved systems of equations and, thus, dynamic models are much more computational time consuming. But compared to quasi-static models they not only add viscous forces, but also have time resolution. The type of the model needs to be chosen based on soil type and flow conditions, depending on local flow properties it is possible to combine both models within the same pore-network solver.

Assuming low flow velocities the models described above deal with Darcian or linear flow regime — volume averaged velocities depend only on pressure gradient thus making permeability (or saturated hydraulic conductivity) independent of pressure differences. However, depending on pore sizes and flow conditions pre- and post-Darcian flow regimes can be potentially relevant to soil processes (Fig. 3). The term pre-Darcian is controversial — here we use it to refer to rarified or nano-confined conditions where Stokes' regime is not valid. Such deviations from the linear relationship result due to diffusion (for low Knudsen numbers — in case flowing molecules interact more often with the walls compared to each other), slip effects on the pore walls (for intermediate Knudsen numbers), and their combination (intermediate diffusion-slip flow regime). In soil processes pre-Darcian flow regime can potentially take place for air flow within sub-micron pores or for water flow within sub-micron pores with organic walls, but requires significant additional research to explore and describe them numerically (due to severe limitations in experimental studies with such pore systems in the laboratory). The post-Darcian regime leading to decreased relationship between flow and pressure gradient occurs due to vorticity originating within the pore space for flow velocities with Re above 1 (Muljadi et al., 2016). Note that such flow is usually not turbulent (in the statical turbulence theory sense) and can be considered to be a transition from Stokes to Navier-Stokes flow regime. Post-Darcian regime may influence the way we model flow within the macropores for the description of the preferential flow (reference to preferential flow chapter). The relevance of non-Darcian flow for soil processes description is an area of emerging research.

Non-Darcian flow processes can be explicitly modelled using MD approaches, but due to computational expenses solution for pores with diameter up to 50 nm can be achieved. For micron size pores some direct modelling approaches can be utilized, but due to their upscaled nature some parameters (e.g., tangential accommodation coefficient) may be necessary to be evaluated from MD or DFT simulations. If direct solution or an empirical model is available, a pore-network model can be parameterized and used for effective simulation on larger modelling domains (Mehmani et al., 2013).

In addition to single- and multi-phase fluid flow problems, pore-scale modelling approach allows simulation of numerous other transport coefficients and physical processes. One relevant example is the dispersion that can be easily simulated on top of velocity distributions resulting from solving Eqs. (1) or (2). To simulate mass transfer a particle tracking approach may be used — the

Fig. 3 Illustration of pre-Darcian, Darcian and post-Darcian regimes and their influence on the transport properties of soils.

“molecules” of the substance are placed within the fluid and are moved on each time step randomly due to diffusion (according to known diffusion coefficient) and along the local flow velocity vector due to advection. Parallel implementations for millions of particles can describe complex dispersion patterns within porous media (Khirevich and Patzek, 2019), including hierarchical structures. Direct solution can be again extended to pore-network models and utilized for computationally efficient mass transport models over huge soil volumes to obtain macroscopic dispersion coefficients. Other transport processes such as heat flow or mechanical properties can be simulated using aforementioned numerical methods, but with different systems of equations solved and, thus, are not considered in detail here.

Examples of the application of pore-scale modelling

To display the power of pore-scale modelling approaches here we shall simulate saturated and unsaturated flow for a single soil 3D image. As an object of the demonstration we chose a well-described soil sample Ah-1 (low porosity) from the work of (Gerke and Karsanina, 2021). The 900^3 voxels 3D geometry of this soil sample and the pore-network extracted with the approach of Gerke et al. (2020) has been already shown in Fig. 2. At first we solve the Stokes equation (Eq. 2) with the help of FDMSS Stokes solver that was exhaustively described by Gerke et al. (2018). The FDMSS solver is an open software and is optimized to perform on a regular machines such as a 3D image with the volume of 500^3 voxels can be processed on a modern laptops and up to 1000^3 voxels with the help of the desktop workstations. The results of the simulations along a single direction are shown in the form of the pressure and flow velocity fields are depicted on Fig. 4. After averaging of these fields one can compute the permeability (or saturated hydraulic conductivity which is essentially the same value normalized by the fluid viscosity and is temperature dependent for water). In addition to classical directional permeabilities it is also possible to compute a full permeability (or K_{sat}) tensor, but producing a physically relevant value for a REV volume soil would require geometrical periodization with the help of stochastic reconstructions (Gerke et al., 2019) or the knowledge of the exact pore geometry around the studied sample is needed otherwise.

For a two-phase flow case we chose a PNM modelling approach due to its computational efficiency for 900^3 voxels volume at hand. After the extraction from the 3D image the pore-network model was passed into a popular open PNM-solver by Valvatne and Blunt (2004). We have modelled the air-water (under room temperature conditions) drainage process with perfect water wetting conditions (0° contact angle) and under quasi-static assumption. The results of the simulations including resulting water retention curve and relative permeabilities for both air and water are shown in Fig. 5.

Here we limited our consideration to the computationally inexpensive methods that are freely available to the public in the form of open codes or free software and can be reproduced by any willing researcher; all visualization was performed with the Paraview software or vtk library.

Existing codes

One of the main messages we want to convey in this chapter is that any interested researcher can manage to start pore-scale simulations with the help of the existing software. Available resources include open codebases and commercial packages — Table 1 summarizes major existing resources and briefly discusses advantages and shortcomings of each potential solution. The information we provide here is not comprehensive, especially considering the vast amount of commercial solutions available, yet we believe that closed source commercial software does not provide a clear methodological way forward and, thus, are not a preferred way of doing

Fig. 4 Pressure and flow velocity field visualization after a single-phase direct flow simulations (using FDMSS free software). These fields are input data for homogenization procedures that allows permeability or saturated hydraulic conductivity (including their full tensorial representations) to be obtained.

Fig. 5 The examples of two-phase (air displacing fully wetting water – drainage) flow simulations within a soil sample including visualizations of different pore filling stages that result in water retention curve and relative permeabilities (or unsaturated conductances).

science compared with codebases extensively described in research papers. We have to admit, however, that the quality of research codes is usually low compared to commercial products. Its usage may also require some programming skills to deal with or improve them to deal with ones current research needs.

Homogenization, upscaling and beyond

As mentioned in the Introduction, pore-scale modelling is able to mitigate numerous shortcomings of the field or laboratory methods to obtain soil physical properties, such as permeability (saturated hydraulic conductivity), water retention curve, relative permeabilities for air and water (unsaturated conductivities), dispersion coefficients. Among others benefits, the modelling approach allows to obtain unsaturated properties much faster than laboratory measurements and with known boundary conditions (e. g., pressure at the outlet), that are usually hard to manage in field measurements. Needless to say, once the 3D structure of the soil sample is known, the amount of modelling experiments that can be performed on this sample is virtually limitless — this is something that is hard to achieve in the laboratory. The ability of pore-scale modelling methods to determine the full tensorial physical properties is especially valuable for homogenization and upscaling (Fig. 1) in order to parameterize continuum-scale hydrological models.

Pore-scale modelling also allows us to homogenize soil volumes that do not exhibit REV properties — this is especially important considering the fact that majority of standard cores may lack representativity in case of structured soils (Gerke and Karsanina, 2021). This ability of pore-scale methods to operate on any volume of soil may also be invaluable in determination of coefficients of exchange between soil matrix and preferential flow paths, e. g., in the form of the macropores (Barbosa et al., 2022a). In addition, some mass transfer parameters, for example, mineral nutrition solution flow from nano-porous organic-mineral assemblages to the plant roots, may only be valid on the very small scale, well beyond the abilities of the laboratory measurements. In such applications, there is no alternative to pore-scale modelling.

Local knowledge of velocities or water-air menisci positions and phase connectivities may be needed to explain the living conditions of microorganisms and to simulate their habitat evolution, organic matter mineralization or CO₂ production processes. Another example could be the modelling of swell-shrink behavior of soils depending on the local availability of water, where water availability and air trapping can be, in turn, affected by the structural dynamics. Classical models for unsaturated parameters, such as the van Genuchten-Mualem model, can be modified to account for hysteresis, but such modifications are purely empirical and fail to account to all possible boundary conditions variations. Pore-scale modelling can describe any history of flow conditions and any number of hysteretic loops. In other words, pore-scale modelling approaches allow us to operate on any size of the modelling domain, at least from above it is limited only by the computational resources available — and this is the limit that requires us to upscale to the continuum-scale models, and to describe the parameters that continuum-scale needs to operate.

Table 1 A brief summary of existing pore-scale modelling resources.

<i>Code or software</i>	<i>Functionality</i>	<i>Advantages</i>	<i>Shortcomings</i>	<i>Reference to the source</i>
OpenFOAM	An open computational fluid dynamics codebase mining to solve numerous (coupled) problems, cross-platform (yet Linux is preferable)	Has a well documented solvers that can be programmed to solve virtually any system of equations	A very steep learning curve with programming skills required, some solvers are based on rather old technologies and are not always state-of-the-art, in general very computationally expensive methods, limited support of block matrices in linear systems	https://www.openfoam.com/ A porous media solver based on OpenFOAM core by Ali Raeini: https://github.com/ImperialCollegeLondon/poreFoam-singlePhase (single phase) https://github.com/ImperialCollegeLondon/poreFoam (two-phase as described by Raeini et al. (2012)) https://palabos.unige.ch/
Palabos	A cross-platform code for single and two-phase LBM flow simulations	A wide variety of boundary conditions, very well documented and robust package with a significant back up of scientific publications	Some programming skills are required to setup computations	
FDMSS	A finite-difference Stokes solver (single-phase flow) software	Very efficient compared to other examples in this table — one can simulate 500^3 voxels cubes on a modern laptop and up to 1000^3 voxels on desktop workstations, very easy to use	The accuracy of the solution is lower than for the LBM method	https://porenetwork.com/download/fdmss/ (Windows version, Linux version can be obtained from the authors on demand) The description and the manual are provided by Gerke et al. (2018)
OpenPNM	A open-source library for pore-network-based simulations — includes the PNM extractor and simulation parts	Easy to start and use python-based code-base	Somewhat rudimentary flow simulations as compared to other codes	https://openpnm.org/ (also includes other libraries such as porespy to characterize porous structures and more, Gostick et al., 2016)
Dong's code	A classical code for maximal inscribed-balls PNM extraction methodology, saves the results into the 'stat-oil' format	A long time leading open-source solution for PNM extraction	Has been shown to have some inaccuracies. The codebase is very hard to manage (even after code improvements performed by Ali Raeini)	https://github.com/ImperialCollegeLondon/pnextract (Dong and Blunt, 2009)
Valvatne's code	A classical code for single- and two-phase simulations in PNMs. Reads in 'stat-oil' format and works perfectly in pair with the Dong's extractor	A long time (and still is) leading open-source solution for PNM simulations	Produces unphysical results in some particular cases, the model within the code is sometimes different from the one described in the paper	https://github.com/ImperialCollegeLondon/pnflow (the original code as described by Valvatne and Blunt (2004) has been significantly refactored and improved by Ali Raeini)
Comsol	A versatile finite-element method commercial software for a variety of simulations, including pore-scale flow simulations (single, two- and three-phases) that can be coupled with other processes, e. g., mechanical deformations	Very well documented with huge learning resources and useful support services	Commercial software with closed code, lacks built-in mesher to convert 3D voxelized images to polygonal/unstructured meshes necessary to produce solutions with Comsol	https://www.comsol.com
Paraview	A current state-of-the-art visualization tool based on vtk library (was used to produce flow and PNM visualization in this chapter)	Very well documented with variety of formats to save data for visualization (easy to implement within ones code or export from major open codebases or commercial software)	Unstable and susceptible to occasional crashes (in case of problems try other version, Linux versions are preferable)	https://www.paraview.org/

The immediate question is “Can one combine the computational power of pore-scale and the efficiency of the continuum-scale models?” This can be achieved by coupling of these two scales into a single model that exchanges parameters — pore-scale provides upscaled physical flow properties, continuum-scale model updates all fluxes or processes within a large modelling domain and returns the boundary conditions (e.g., pressures, saturations) back to pore-scale to re-calculate the properties. As far as we know, Heiba et al. (1986) were the first to propose such a coupling. However, the implementation for such a coupling is non-trivial and only some simple 1-D preliminary studies are known (Sheng and Thompson, 2013). In addition to dynamic coupling, such models could include any number of scales in a Russian doll manner — continuum-scale links to pore-scale, which in turn is parameterized by MD/DFT models. Such linking can also be accelerated with the help of the machine learning. While still looking somewhat distant future, such coupled multi-scale multi-physics models are the most appealing approach to describe the multitude of soil processes on all necessary scales from nm to meters.

Summary and outlook

In this chapter we briefly described the current state of pore-scale models for soil processes with the focus on flow and transport problems. While there are tools that can solve flow governing equations (Navier-Stokes type equations or their simplifications), their application in soil physics is very limited, likely for historical reasons — pore-scale simulations received a lot of attention in petroleum engineering and related disciplines, while soil was for long considered to be a complex living substance that is hard to be described numerically. With the development of soil structure imaging methods on all scales (XCT imaging, thin-sections and FIB-SEM), a realization of a fully 3D digital model of soil structure that can account for dynamic changes and multi-phase soil constituents is a matter of time and effort (Karsanina et al., 2021). With such a model at hand, building a multi-scale pore-network model for large scale flow and transport simulations is only a practical challenge with all technological aspects already known.

In Table 1 we have summarized some major open or free and commercial tools for pore-scale simulations. With such tools any soil scientists can incorporate pore-scale modelling into her or his research. However, some care has to be taken while doing so — one needs to understand the underlying physics to make sure the correct model and parameters are chosen for the task.

In soil physics applications a lot of additional work is actually needed to verify pore-scale models and to understand which physical phenomena, for example, nano-scale transport, is important for which physical property or process. Such work is complicated by a gap between the volumes of soil operated upon in laboratory methods and pore-scale models; but this gap has been shrinking for the last 10 years and can be completely eliminated with the help of multi-scale pore-networks extracted from fused 3D images (Karsanina et al., 2018).

In summary, we still tend to think that pore-scale modelling is an evolving technology. By saying this we mean that to apply it to numerous soil problems “out of the box” a lot of addition research is necessary — one needs to make sure that all processes relevant to soils (as compared to hydrocarbon bearing rocks) are properly incorporated into the model. With the vast potential and ability to explore different scales and processes that pore-scale modelling provides, we are confident that such tuning is a matter of 5–10 year. For a variety of soil processes mentioned here, pore-scale modelling simply has no alternatives; moreover, it allows to study any volume (especially small areas or volumes dominated by sub-micron porosity) with any boundary conditions — something that is close to impossible to achieve in laboratory or field.

Acknowledgments

We thank our colleagues Dr. Nickolay Evstigneev and Dr. Aleksey Khlyupin for very fruitful flow modelling discussions, Rustem Sirazov, Andrey Ananov and Mikhail Gomorev for the help with figure creation.

Abstract

Soil texture is one of the most fundamental and longest recorded soil properties. It refers to the balance between the various size fractions of the soil's solid constituents. This chapter summarizes commonly used and emerging methodologies to determine, and systems to represent soil particle-size distribution and to classify soil texture. Given the diversity in methodology as well as classification systems used internationally, we also address data compatibility issues and harmonization options. We close the chapter by presenting some of the classic uses of soil texture information.

Glossary

Bulk density The total mass of solids per unit soil volume.

Liquid limit The water content at which the soil changes from a plastic state to a liquid state.

Plasticity The soils ability to undergo deformation without cracking.

Plastic limit The moisture content at which soil can no longer be remolded without cracking.

Porosity Total volume of pores, whether filled by the liquid or gas phase, per total volume.

Specific surface area The total surface area of a material per unit of mass.

Void ratio The ratio of the space occupied by the voids to the space occupied by solids.

Particle-size distribution or grain size distribution or gradation Refers to the abundance of different sizes of individual soil particles.

Atterberg limits Proposed by Albert Atterberg (1846–1916), the Plastic Limit (PL) and Liquid Limit (LL) correspond to soil moisture levels at which the soil's consistency changes.

Brownian motion The random motion of particles suspended in a fluid medium.

Pedotransfer function A relationship (e.g., equation, table, decision tree) from which certain soil properties can be estimated from other soil properties.

The A-line It is an empirically chosen line on the plasticity chart that separates clays (soils that fall above A-line) and silts (soils that fall below the A-line). The A-line is given by the equation $PL = 0.73(LL - 20)$.

Key points

- Soil texture, deduced from a field test or soil particle-size analysis, is an essential soil property that is a product of soil formation and determines or influences key functional soil processes.
- Soil particle-size distribution is determined by a variety of conventional and new methods that are often based on different measurement theories and underlying assumptions and present substantial challenges of data compatibility.
- A uniform textural classification of soils world-wide is hindered by the diversity of measurement techniques and sample preparation practices being used, as well as variations in the fraction limits that are used to define the three basic textural fractions: sand, silt and clay content.
- Soil texture is used to infer a variety of other soil properties that are often more difficult to determine, and is frequently used to help delineate areas of similar hydrological behavior in large scale modeling applications.

Introduction

Soil consists of a collection of particles that differ widely in size and shape. Some particles are coarse enough to be seen easily with the naked eye, while others are so small that they can only be seen with powerful microscopes. The term ‘soil texture’ refers to the relative proportion of the various sizes of mineral soil particles. It is usually expressed with reference to the most dominant particle sizes found in the soil and has both qualitative and quantitative connotations.

Qualitatively, ‘soil texture’ refers to the ‘feel’ of the soil material. When rubbed by hand, the soil can give a feel that ranges from coarse and gritty to fine and smooth. Experienced soil classifiers can press soil into their hands and tell its texture, coarse or fine, or gradations in between. This test is often called ‘field texturing,’ ‘hand texturing’ or ‘feel analysis.’ A guide to performing a feel analysis is provided by USDA-NRCS (USDA-NRCS, website link). Gee (2005) warns that the expressions ‘light soil’ and ‘heavy soil’ are frequently used to characterize the general physical behavior of different soils. A coarse-grained, sandy soil tends to be loose, well-aerated, and easy to cultivate, therefore it is called a ‘light soil.’ A fine-textured soil tends to absorb water easily and becomes plastic and sticky when wet, and tight, compact, and cohesive when dry, therefore it is called a ‘heavy soil.’ These terms are misleading, since coarse-textured soils are generally denser, and have smaller total porosity than fine-textured soils, and thus are heavier rather than lighter per unit volume. Table 1 shows the range of densities and porosities that are typical for soils of various dominant textures. These values can vary, however, within a wide range, and it is noted that soil use and management can influence them substantially in both the short and long term.

Quantitatively, soil texture refers to the relative proportions of various sizes of soil particles, sometimes called ‘size separates,’ which is the main subject of this chapter.

Soil particle size measurements

The size of soil particles can vary over 6 orders of magnitude, ranging from large stones and rocks (greater than 250 mm in size) to tiny, submicron clays (less than 0.0001 mm). The shape of soil particles also varies widely. Particle shape is often an indication of the mineral assemblage and the degree of soil weathering that has taken place. For beach sand, composed of quartz, particles are uniformly rounded and almost spherical. In contrast, most clay materials are far from spherical, many being platelets, looking more like playing cards (e.g., kaolinite) or tubes (e.g., halloysite) than marbles. In spite of the variation in shape, soil particles are sized according to their ‘effective’ particle diameter. Because of the huge size range, no single method is optimal to measure all particle diameters. The analysis is most commonly referred to as analysis of particle-size or grain size distribution. Size measurements depend on effectively separating the soil into primary particles. Methods for soil analysis consist of disaggregation by washing, exposing the specimen to vibration (physical or by ultra-sound), or otherwise dispersing the soil into single units. Typically, any larger stones (cm size range) are measured directly by a tape, a ruler, or a caliper. The stony, gravelly and sandy fraction—consisting of particles in the mm size range down to approximately 0.05 mm are generally sieved, i.e., washed through a nest of screens over a given period of time, while the proportion of particles smaller than 0.05 mm is determined by sedimentation or techniques based on light-scattering.

Table 1 Typical bulk densities and associated pore system properties for soils of various textures (Gee, 2005).

Description	Bulk density (g cm^{-3})	Porosity (cm cm^{-3})	Void ratio (cm cm^{-3})
Clay	1.20	0.54	1.17
Loam	1.40	0.49	0.96
Sand	1.60	0.39	0.64

In soil science, by convention, only the fraction that consist of particles smaller than 2 mm are considered for the expression of soil texture. This is reflected in most, if not all textbooks and measurement protocols, by stating that the soil should be sieved to 2 mm prior to further analysis. The fraction coarser than 2 mm is then considered as a gravel or stone fraction, depending on the size of particles and the classification system used. It is noted that some historical data from some Eastern European countries adhered to a system in which the limit between sand and the coarse fraction was either 1 or 3 mm, but they have now adopted the 2 mm system.

Sample pre-treatment for fine earth measurements

In natural soil, particles are bound by both organic and inorganic agents into various sizes of soil aggregates. Prior to the particle-size analysis, those binding agents must be removed to release the elemental particles from the aggregates. For tropical soils or soils with large organic, iron, or aluminum contents, special treatments are deployed to remove these binding agents and release the primary particles. Soils of volcanic ash origin are notorious for aggregation, and the chosen pre-treatment by chemical or mechanical dispersion can significantly affect the amount of clay released. In one test, researchers have demonstrated that the clay content (i.e., the sum of particles smaller than 0.002 mm) of a volcanic ash soil varies from 1% to 56% depending on the amount of pre-treatment imposed on the sample (Gee, 2005). Some tropical soils consist largely of clay-size particles yet behave much like sands, in terms of their water-storage and related physical properties, because of the high degree of natural aggregation.

The classical approach to sample pre-treatment is that the sample is stirred in water containing a dispersing agent, such as sodium hexametaphosphate or sodium pyrophosphate, which swamps the clay surfaces with sodium, causing dispersion of the clay materials and accelerating disaggregation. Prior to this step, laboratories also often remove soil organic matter using hydrogen peroxide, sodium hypochlorite or disodium peroxodisulfate (Mikutta et al., 2005), and remove the primary inorganic binding agent, calcium carbonate, using hypochloric acid. The applicable ISO standard (International Organization for Standardization [ISO], 2020) leaves space for interpretation of these steps, and since they can be time and labor-intensive processes, in which experience may also be important, their application in different laboratories may differ. *At the time of writing of this chapter*, the FAO Global Soil Laboratory Network (FAO GLOSOLAN) is working on a better defined standard operating procedure (SOP) to be recommended for both the sample pre-treatment and the measurement of soil particle size distribution using the pipette and hydrometer methods, which is expected to help fill this gap.

Methods, such as laser diffractometry, use a much smaller amount of soil sample than sedimentation methods, and the measurement is based on a different background theory. For this analysis, laboratories still use sodium hexametaphosphate for sample pre-treatment, often in combination with physical dispersion using ultrasonic agitation.

Frequently used measurement methods

The pipette and hydrometer methods

Most particle-size measurements on the fine soil fraction (i.e., silt and clay fraction) rely on sedimenting a soil suspension (Gee and Or, 2002). Stokes' law for viscous drag on a settling spherical object is combined with buoyant and gravitational forces to obtain the settlement rate. Combining forces and solving for the particle velocity yields:

$$v = d^2 g (\rho_p - \rho_w) / (18\eta) \quad (1)$$

where d is the equivalent particle diameter, g is gravitational acceleration, ρ_p is particle density, ρ_w is the solution's density, and η is the solution's viscosity.

Knowing settlement depths allows for a straightforward calculation of the effective particle diameter. In this understanding, the pipette technique involves taking physical samples from given depths and after given settlement periods, while the hydrometer method relies on estimates of the effective density of the suspension as particles of various size settle.

Fig. 1 shows the pipette method and Fig. 2 shows a typical hydrometer used for soil-suspension density measurements. This equipment is relatively inexpensive and readily available. For routine analysis in soil, sedimentation, and engineering laboratories, the pipette and the hydrometer are the standard tools for fine-fraction analysis. Various laboratories typically determine 3 to 8 points on the particle size distribution curve at various pre-determined cut-off points that are then used to determine the texture class of the soil and can be fitted with a lognormal or other curve type.

The integral suspension pressure (ISP) method

There has been interest in developing a measurement method that is based on the same theory, Stokes' law, but is more automated and fine-tuned than the pipette or hydrometer methods. Initiated by Nemes et al. (2002), a research group in Hungary introduced a prototype (named ASTA, Kovács et al., 2004, 2006). Later, the method was further refined into the *integral suspension pressure* (ISP) method and successfully commercialized by Durner et al. (2017) and by Durner and Iden (2021) after further upgrades.

The development of sensory technology in the 2000s allowed the detection of very small changes in pressure at a given point in a suspension as particles of different sizes settle over time. Coupled with that technology, an integral calculation was programmed into the measurement software that interprets the pressure signal into a quasi-continuous soil particle-size distribution curve. This interpretation is limited by the same assumptions (e.g., particle sphericity, independent settling) that also apply to the pipette and

Fig. 1 Schematic of pipet apparatus and stand for sedimentation analysis of soil-particle size. Reproduced with permission from Syvitski JPM (Ed.) (1991) *Principles, Methods, and Application of Particle Size Analysis*. New York: Cambridge University Press.

hydrometer methods. It is noted that for the full particle-size curve, the sand fraction still needs to be determined by sieving, since that fraction settles too quickly in a water-based suspension. When the measurement is initiated after shaking, sedimentation of the sand particles already starts in the first c.a. half a minute when the suspension is still in turbulent motion, and it is difficult to obtain a stable pressure signal. Nemes et al. (2020) tested and demonstrated some of the sensitivities of the method.

Light scattering, laser diffractometry (LDM)

In recent decades, the need for diagnostic tools in soil genesis and mineralogy have led to more sophisticated techniques being developed and tested. Several techniques have been investigated that are based on other theories, such as changes in an electric current or the scattering of a light beam by individual soil particles that are channeled through a sample cell in a dilute suspension.

Named after Wallace H. Coulter, the 'Coulter counter' technique is based on particles changing the electric current in the sample cell as they pass through. The technique has been used by numerous groups in soil and sediment research (e.g., Walker et al., 1974), but this technology has been more widely adopted in the medical field (e.g., hematology).

Laser-light scattering techniques, such as LDM, are gaining popularity in soil science to obtain size distributions of soil materials. Fig. 3 shows the primary components of a laser light-scattering device. Multiple laser diffractometer models are now on the market and soil laboratories worldwide make larger up-front investment costs by purchasing such devices that save on later measurement time and costs. Several technical aspects and limitations have been documented with respect to device settings, construction of dispersion units and the varied quality of homogenization of samples when different fractions are represented in different ratios, respectively, which are good to consult prior to working with the method (e.g., Ryżak and Bieganski, 2011; Sochan et al., 2012; Polakowski et al., 2015). Subsequently, Messing et al. (2021) and Svensson et al. (2022) highlighted the difficulties in comparing particle-size data obtained by different laser diffractometer models, hardware and software settings and the diversity in sample pre-treatments.

Compatibility of measurements using methods based on different measurement theories

Concerns have been raised about the compatibility of data obtained using different measurement techniques. Many studies have now reported that data obtained by laser diffractometry (LDM) and by sedimentation type methods (SM) do not compare well, and

Fig. 3 Laser diffraction particle-size analyzer showing the primary components: light sources, sample, focusing lens, detector, and processing system. Reproduced with permission from Syvitski JPM (Ed.) (1991) *Principles, Methods, and Application of Particle Size Analysis*. New York: Cambridge University Press.

various conversion or adjustment options have been suggested (e.g., Makó et al., 2017; Yang et al., 2019; Svensson et al., 2022). Various reasons have been cited for such discrepancies, such as differences in the measurement theory, the representation of each particle fraction in dilute (LDM) or denser (SM) suspensions, that certain assumptions are invalid (e.g., sphericity of particles, independent motion of particles and the absence of Brownian-motion in the colloid phase). No agreement has yet been reached on the basis for data conversion.

The reason for the discrepancies in measurements lies in the combination of these cited factors. Soil particles are not spherical—often far from it—although the measurement methods assume that they are. This leads to uncertainties and biases in the subsequent calculations in different ways. In the sedimentation cylinder, non-spherical particles will be exposed to different drag on their sides and will tend to orient with the larger surface perpendicular to the direction of sedimentation, similar to how leaves fall from trees, and will not sediment steadily and according to their equivalent size. The same non-spherical particles provide different light-reflection patterns depending on their orientation at the time of passing the detection chamber driven by turbulent flow, and their sizes may therefore be misjudged. While the agreement in the sand and silt fraction appears to be rather linear, the discrepancies appear to be less well describable in the clay fraction, which suggests that additional factors, such as the presence of Brownian motion in the sedimenting suspension as well as potential differences in sample pre-treatment may play a role.

It is well documented that measurements by the LDM method and by the sedimentation type methods cannot be directly compared, so they need some kind of conversion or adjustment factor (Svensson et al., 2022). The same authors pointed out different approaches proposed for this in the literature. Typically, authors suggest an alternate reading point by LDM (e.g., a value in the 4–5 μm range) that should be understood as the reading that best approximates the clay content obtained by the conventional pipette method, but the recommended value varies study-by-study. These differences are most likely driven by differences in clay mineralogy of the soil samples (i.e., shape of the smallest particles), differences in hardware and their settings, and undoubtedly differences in sample pre-treatment. Finding an advanced conversion method will be necessary to avoid fragmentation in our methods and compare data obtained internationally. Without proper conversion, there is a risk of introducing bias to the obtained particle-size distribution curve (i.e., mostly underestimating clay content vs. the sedimentation type methods) that may further result in mis-classification of the soil in question, as demonstrated by, e.g., Makó et al. (2017), Yang et al. (2019) and Svensson et al. (2022).

It is technically possible to obtain data that appear to align well despite the use of a multitude of methods, such as sieving, sedimentation, and light scattering methods (e.g., Wu et al., 1993). It appears that with appropriate pre-treatments and method calibration, data compatibility can be achieved, but so far this remains a challenge in the fragmented practical laboratory work where different local or national standards, as well as cost- and work-time reduction efforts, frame some of the choices made when preparing samples or making measurements.

Compatibility of measurements using methods of similar measurement theories

Initial indications concerning the performance of the integral suspension method compared to the traditional sedimentation type methods are mixed. Acevedo et al. (2021) and Messing et al. (2021) reported sizeable biases between those methods, while Nemes et al. (2020) reported near-perfect alignment in the sand and silt fractions, but only poor correlations, although no substantial bias, in the clay fraction, despite the measurements having been performed in separate laboratories by separate staff. In the study of Nemes et al. (2020) the same sample pre-treatments were closely adhered to, whereas in the other two investigations, a variety of nationally recommended sample preparation methods were mixed with that recommended in ISP's documentation. This points toward the significance of sample pre-treatments when it comes to using ISP compared with other sedimentation type methods. While more supporting data should be collected, it is currently recommended that laboratories that change between sedimentation type methods keep following their regular sample pre-treatment steps to keep their new data *backward-compatible* with their historical data.

Advantages and disadvantages of different novel measurement techniques

When we compare data from ISP, LDM or any future technique, all such assessments and statistical evaluations typically assume that the data acquired using the pipette or hydrometer methods are correct and error-free. This is likely not the case, due, among other factors, to the assumed spherical shape rarely being met by natural soil particles. In addition, different laboratories often follow different sample preparation protocols that may result in different degrees of disaggregation, causing variation in the measurements. Nevertheless, *backward compatibility* with historical data is desirable, and hence for now, we make the practical assumption that those measurements are correct.

Measurement effort and cost

Beyond the compatibility of measurements, another key driver behind method development is the desire to increase the efficiency of data acquisition—i.e., the prospect of faster, easier, cheaper collection of data. To that effect, users have reported on the practical considerations needed to be taken into account when planning to operate one of the novel techniques.

LDM requires a substantial up-front investment, which is increasingly being made by laboratories in exchange for substantially cheaper operating costs—primarily in the form of saved work-time. Work-time is saved primarily because sample preparation is usually reduced by the highly automated nature of the technique. Moreover, using light-scattering techniques the solution does not need to sediment over time. However, users typically prefer to run replicate measurements. Because of its low running costs, the LDM technique is gaining popularity and its application may provide better *forward compatibility* with future data collections by many other users.

The ISP method is a computerized, semi-automated technique for PSD determination. It yields high resolution data with a distribution curve fitted to it. However, it still requires substantial human interaction and measurement time. Early indications are that available ISP versions appear to provide *backward compatible* data with conventional methods if the user applies the same sample pre-treatment, which is usually an elaborate process. Applying this technique requires the sedimentation of particles as conventional methods do, and it also requires the user to manually sieve the sand fraction and enter this data into the software, which are added work-time components. It is also noted that the ISP technique is sensitive to temperature or air-pressure fluctuations in the first minutes of the measurement (Nemes et al., 2020), that needs to be controlled by proper planning and potentially some minor investments to avoid a biased pressure signal propagating through the measurement. The technique, however, promises to provide the best option for both backward and international compatibility.

The added value of continuous data—International compatibility

A great advantage of both the ISP and the LDM methods is that the data obtained are nearly continuous and allows reading off the curve at any size limit without interpolations or post-processing required. If the only goal is to provide sand, silt and clay fractions according to a single classification system, a continuous PSD curve has minimal added value. However, with the growing internationalization of environmental and climate research, there is an ever increasing need to standardize the collection of new data, or at a minimum to make it easy to collect *internationally compatible* data. A continuous PSD curve promises to allow efficient direct interpretations according to different national and international systems simultaneously, without the need for elaborate interpolations that often hinder international collaborative efforts (e.g., Nemes et al., 1999). The complexity and some consequences of having to interpolate existing soil PSD curves is addressed below.

Particle size and textural classification schemes

Particle size schemes

For applications in agronomy and soil-science, the size-fractions of primary interest are those smaller than 2 mm due to their water retention characteristics. This texture range is usually represented by 3 main size separates, sand, silt and clay, where the sand and silt fractions are often further divided into sub-fractions (e.g., very fine, fine, medium, coarse and very coarse sand). However, different national and international systems exist for establishing the definitions and measurement. Fig. 4 presents an overview of several particle size measurement sequences in practical use in a number of European countries. The main system is recognized by FAO and the US Department of Agriculture (USDA). The system recognized by The International Union of Soil Science (IUSS) differs in the definition of the upper limit for the silt fraction (being defined at 0.02 mm by IUSS and 0.05 mm by FAO/USDA). Nevertheless, there are several other size cut-offs between silt and sand content in practical use world-wide, such as 0.06 mm in Scandinavia and Great Britain, or 0.063 mm being used dominantly in Germany. Note that the size separates have arbitrary size limits, and for the most part the differences between schemes appear to be relatively small.

Other systems have existed or still exist that make data comparison and conversion much harder if not impossible. As seen in Fig. 4, some countries defined soil clay content at a different limit (e.g., as <0.001 mm) to most others and international systems (i.e., <0.002 mm), but with proper interpolation—the topic being addressed below—an estimate of the 0.002 mm fraction can still be made. It is, however, a lot more challenging or close-to-impossible to give an estimate of any fraction according to the FAO-USDA system when the entire fine earth fraction was determined on sizes <1 mm, as was the case historically, e.g., in Poland (Ryzak and Bieganski, 2009) or Russia. Given that in such cases the 1–2 mm fraction was considered as ‘course fragments,’ it was discarded and therefore it would require extrapolation, rather than interpolation to achieve compatibility with more broadly used systems.

Fig. 4 Particle-size limits used by countries contributing data to the HYPRES database. Reproduced with permission from Nemes et al. (1999) *Geoderma* 90(3–4): 187–202.

Textural classification systems

Since soils rarely consist of a single size fraction, textural classification is based on different combinations of size separates. There have been dozens of different schemes proposed and used over the last ca. 150 years that are as diverse as the applications for which the textural data are used. Different disciplines often have their primary interest in a particular particle size range and present different practical or theoretical arguments to support their systems (Blott and Pye, 2012). Here we focus on the primary classification systems used to classify agricultural soils and later use these to demonstrate primary data conversion issues.

Fig. 5 illustrates four different soil texture triangles in current use in four data-rich countries. It is often not straightforward to convert the textural class of a soil from one system to another. For example, in the German system, silt content is defined as the fraction (weight percent) of particles in the size range of 0.002–0.063 mm, whereas in the other systems depicted in Fig. 5 it is defined as the fraction between 0.002 and 0.05 mm. A conversion of particle size data is necessary to convert between textural classification systems. Nemes and Rawls (2006) demonstrated that lack of conversion will increase the risk of introducing bias in any follow-up application, while an interpolation-based conversion introduces some random error but reduces the chances of bias in subsequent applications.

Conversion of data using interpolation

The internationalization of environmental research has presented a growing need to harmonize soil particle size data and present them according to a uniform textural classification system. Several researchers have tested various models (curve types) to fit part or the entire particle-size distribution curves (e.g., Hwang et al., 2002; Bayat et al., 2017) which could be used to make interpolations. In the work of Nemes et al. (1999) the authors tested several methods to achieve such a task for a large European database. The popular log-linear interpolation is simple to use but was proven unreliable when applied to a broad range of soils, especially when only the sand-silt-clay triplet was available. Among the tested methods, a free-form spline function and a k -nearest neighbor (k -NN) type pattern-recognition algorithm were better, more reliable alternatives (Fig. 6). The k -NN algorithm calculates the weighted average of the appropriate fraction from a limited number of similarly shaped curves in a large external database, and assigns it as the

Fig. 5 Examples of different soil texture triangles used in four different countries. The US texture triangle is widely used in the World. Conversion between the US, Canadian, Australian and the FAO (not shown) systems requires only re-classification, while conversion to or from the German system requires data conversion or interpolation first. Moeys (2018—https://cran.r-project.org/web/packages/soiltexture/vignettes/soiltexture_vignette.pdf) provides R scripts to produce texture triangles based on different classification systems. Reproduced with permission from Bormann (2010) *Geoderma* 157: 142–153. DOI: <https://doi.org/10.1016/j.geoderma.2010.04.005>.

estimate. The approach has been successfully applied to harmonize particle-size distribution data in the European HYPRES (Wösten et al., 1999) and EU-HYDI (Weynants et al., 2013) databases, as well as in collaborative EU projects (e.g., H2020 OPTAIN—www.optain.eu). Blott and Pye (2001) and Moeys (2018—https://cran.r-project.org/web/packages/soiltexture/vignettes/soiltexture_vignette.pdf) offer conversion tools that can use various interpolation possibilities, however, along with Nemes et al. (1999), urge caution in the use of log-linear interpolation.

Irrespective of which method is used, the estimations become less reliable if the measured points are sparse. This adds uncertainty to the estimated size-fraction and as a consequence to the texture class that a sample falls into. However, the occurrence of random misclassification is seen to be less problematic than if textural classification is systematically shifted, due to not interpolating and converting data, to the appropriate system (Nemes and Rawls, 2006).

In some cases, the missing particle-size data point is at one of the ends of the distribution curve, in which case some type of extrapolation is required to fill the gap. Extrapolations beyond the measured data range should generally be avoided, however, in some cases that is the only option for integrating data into a larger data pool (e.g., that of a country into a region or continent). Should extrapolation be necessary, all efforts should be made toward testing the procedure and quantifying its uncertainty.

Fig. 6 Sensitivity of 4 interpolation procedures to data scarcity around the point to be interpolated. The tighter the points around the $Y = 0$ line, the more reliable a method is. The greater the gap between measured data points (X axis), the greater the interpolation uncertainty gets. The 'similarity' technique here and the 'k-nearest neighbor (k-NN) algorithm' referred to in the chapter text are identical. Reproduced from Nemes et al. (1999) *Geoderma* 90(3–4): 187–202.

Attempts at unification of soil particle-size measurements

It has been recognized that local solutions are necessary but not sufficient to resolve global environmental and climate issues. Research is therefore being internationalized, and the lack of a unified system to measure basic soil data has been identified as posing a challenge to international scale environmental research.

As summarized by [Blott and Pye \(2012\)](#), as early as 1962, a number of committees and working groups had been established in an attempt to reach an agreement on a common system of particle size classification. The Soil Science Society of America (SSSA) established a 'Particle Size Distribution in Soils' committee, while the Society of Economic Paleontologists and Mineralogists (SEPM, now the Society for Sedimentary Geology) appointed an 'Inter-Society Grain Size Study' committee. A series of meetings and workshops were held, with representatives from several societies, including SSSA, SEPM, ASTM, the Geological Society of America, the Highway Research Board, AASHTO and others. Despite all the efforts, with so many organizations involved it is perhaps not surprising that an agreement was not reached. Each organization had already too much invested in their respective classification systems by that time. SSSA and SEPM published their own position papers on the issue ([Committee on Particle Size and Distribution, 1967](#); [Tanner, 1969](#)). The latter, presenting the opinion of sedimentologists, outlined strong support for the phi scale, citing a number of major advantages: geometric basis, equal spacing, simple nomenclature, fine subdivisions, wide range of sizes and wide acceptance. Neither this direction, nor the use of the geometric mean particle diameter and its standard deviation gained traction in agricultural and environmental soil science beyond their occasional use ([Shiozawa and Campbell, 1991](#)). The latter approach assumes log-normality of the data and can work across measurement systems.

More than half-a-century later, the situation has not changed much: growth in the number of available measurement alternatives, sample pre-treatment and equipment setup options outpaces efforts to reach consensus over measurement standards and

protocols. Both the European SOPHIE initiative (<https://www.wur.nl/en/article/soil-program-on-hydro-physics-via-international-engagement-sophie.htm>) and FAO's Global Soil Partnership Network (FAO GLOSOLAN, <https://www.wur.nl/en/article/soil-program-on-hydro-physics-via-international-engagement-sophie.htm>) are engaged in developing common data acquisition protocol(s) for soil physical measurements, among them for obtaining soil particle-size distribution data.

The quest is challenging in multiple ways. As seen from the experience in the 1960s, investments made in their measurement standards and extensive data collections prove too important to each society or country to agree to changes, and risk losing *backward compatibility* to existing data. It is important to keep in mind, however, that some novel methods may prove to be sufficiently cost efficient, and may become the gold standard in the future—with or without providing compatible data today.

Use of soil texture data to infer other soil properties

Soil texture is one of the most fundamental properties of both the saturated and the unsaturated zones of the Earth's crust. It is one of the first properties that is measured and that has been mapped worldwide, despite the several different particle size scales and size class terminology schemes recognized in, e.g., sedimentology, geomorphology, soil science, ecology and civil engineering.

The significance of soil texture in determining other soil properties comes from the large size differences in the different fractions. For example, by definition, a sand particle is 100 s or 1000s of times greater in diameter than a clay particle, which makes it simple to depict that the size of the pore space between neighboring particles can differ by up to several orders of magnitude, and the surface area of the same mass of clay can be about 10,000 times more than that of the same mass of sand. Add to this that different clay mineral types have different shapes, specific surface area, and chemical reactivity to appreciate that the type and abundance of the size fractions will determine most of the soil's chemical properties and its response to changes in its environment.

Another important factor in the soil's functionality is its ability to store and exchange air and fluids (i.e., water, solutes, pollutants). The size distribution of particles has long been understood to influence the sizes of pores in the soil. Understanding physical laws such as Darcy's and Poiseuille's laws of flow or the Young-Laplace equation of capillary forces (see relevant other chapters) it should be easy to deduce that soils of different pore systems—both in terms of sizes and their complexities—will result in media that have different conductive and storage properties for both air and organic or inorganic fluids. It is not easy to make translations, such as how much clay it takes to equal a unit of silt or sand, or to determine to what extent different fractions have an effect on a particular soil property of interest. In addition, factors already mentioned like mineralogy, chemical and biological properties as well as the aggregation of particles complicate matters to the point that the use of particle size data to infer other soil properties often requires both (1) a good degree of empiricism and (2) the use of additional soil information. Therefore, it should not be too surprising that texture data alone do not generally relate directly to other fundamental physical properties.

Inference to pore-size distribution

It has been perceived for a long time that most soils exhibit log-normal PSD characteristics. Much has been published about the fractal nature of soil PSD and the possibility that the fractal dimension of PSD is related to an equivalent pore-size distribution that is then subsequently used to obtain estimates of hydraulic properties from those parameters (Gee, 2005). It has, however, been shown that many soils are actually multifractal, i.e., they do not present the same fractal dimension over the entire particle-size range, and therefore this direct linkage between soil PSD and its hydraulic properties has lost traction.

Nevertheless, the PSD curve still constitutes one of the basic soil characteristics and are useful toward diagnosing the origin of a soil, or in the empirical estimation of numerous physical, chemical and hydraulic soil properties. Since types of particle associations typically come with dominantly predictable pore-size distributions as well, the PSD curve is still useful as a proxy to describe pore system properties and predict fluid retention and conductivity properties of the soil—even if in a less direct sense.

Use of texture data to estimate soil hydraulic properties

Soil scientists have used soil texture information to make qualitative judgments about a number of physical properties for a long time, but to use texture for quantitative inferences became main-stream only decades later.

One of the main uses of soil texture information in agronomy and environmental soil science is through inference to soil hydraulic properties—primarily to soil water retention and hydraulic conductivity that are required to parameterize process-based simulation models concerned with, e.g., agro-hydrology, crop production, erosion processes, water and nutrient transport in the landscape, and land-surface processes at the regional to global scales. Since the late 1980s, the umbrella term *pedotransfer function* (PTF) is used to refer to such inferences. There is rich literature on this subject summarized in a compendium and extensive review by Pachepsky and Rawls (2004) and Van Looy et al. (2017) respectively.

There are many types of PTFs distinguished in the literature based on their inputs, outputs, underlying algorithms, etc. Here we highlight the two most basic PTF types, i.e., class and continuous PTFs. A class PTF is essentially an average of some soil property within a group of soils, typically a texture class, while a continuous PTF utilizes detailed particle-size data of each individual PSD curve separately. A class PTF returns the same estimate to each sample within the same class. It is noted that because the allocation of texture classes is rather arbitrary, there is no guarantee that such class boundaries are optimal for the functional grouping of soils. In fact, this approach has been challenged by Bormann (2010) and Twarakavi et al. (2010) who both presented alternate 'classes' that provide a more effective grouping by the hydrological functioning of soils. Continuous PTFs work with sand, silt and clay

contents of each sample and return different estimates for different soils, but it is easy to depict from the literature that more successful PTFs use not only PSD but additional inputs, such as soil bulk density or organic matter content, among other options.

Here we repeat that soil texture or PSD information is the first and most basic input to those estimation functions. It is noted that the notion behind pedotransfer functions is that they relate *available or easy to measure* soil physical properties to other, *difficult to measure*, soil properties, such as soil hydraulic properties. However, today the complexity and effort it takes to obtain reliable and comparable PSD data is underappreciated. When such estimation functions originated, mostly in the 1980s, there was a large pool of conventionally measured soil texture and particle size data available for exploration, and textbook knowledge was followed up by the successful derivation of estimation functions using soil texture or PSD as their input. Since then, limitations in the information content of soil texture and PSD have been explored, while their determination in practice has seen unprecedented diversification in methodology. Further progress in PTF-related international research is expectable only if we succeed to harmonize existing data and standardize measurement methodologies for future measurements to achieve both backward and forward data compatibility.

Limited success in estimating hydraulic conductivity

It has been increasingly recognized that PTFs have chronically failed to give reliable estimates of soil saturated hydraulic conductivity. This functional soil property is among the most variable properties of soil—if not the single most variable one—both spatially and temporally. It is mostly driven by the unique architecture of pores, especially macro and meso-pores, which are driven primarily by soil structural properties, rather than soil texture. Indeed, aggregation of the inorganic and organic constituents of soil drives the formation of the soil's 'expressed' pore architecture, which can then be modified on varied time scales by natural factors, such as rainfall, the activity of soil fauna as well as manifold human-induced interventions, including tillage, compaction, crop management, application of amendments. Yet the measurable PSD and soil texture does not change. The spatial arrangement of soil solids (soil structure) is the first thing that is destroyed during sample preparation for soil texture analysis, leaving the user with only limited information on the pore-size distribution of the soil. The fine, micron to sub-micron scale pore-system is rather predictable from the soil's clay and fine-silt content, but that information only explains part of the unsaturated functionality of the soil, but adds very little to its saturated hydraulic conductivity, which is driven by the structural (10s of microns to mm and cm scale) pore system's properties (e.g., its abundance, connectivity, tortuosity). Since the broad, quantitative representation of soil structure is still unresolved, the estimation of this property on the basis of soil particle-size data remains a challenge.

The tumble effect of misrepresenting soil texture

As noted in previous sections, the choice of PSD measurement method, choice of sample-preparation and measurement protocol, as well as the need for data interpolation all introduce certain degrees of uncertainty. Part of that uncertainty can be random, but very often a notable—often strong—systematic component (bias) is seen. The primary risk of systematic deviations in the representation of PSD is the misrepresentation or misclassification of soils by their texture. Examples have been shown by [Yang et al. \(2019\)](#), [Acevedo et al. \(2021\)](#) and [Svensson et al. \(2022\)](#) for cases when textural misclassification occurs as a result of differences in measurement theories or sample preparation choices, and by [Nemes and Rawls \(2006\)](#) who studied the case when misrepresentation is a result of lack of data interpolation and the resulting misuse of textural categorization.

If soil texture is systematically misrepresented, resulting estimations will also be misrepresented in a domino-like effect. This can be problematic both in small scale studies in which fine differences in flow processes are studied, as well as in large scale (catchment to global scale) studies that use class PTFs to represent soil hydraulic properties. In the latter case, systematic under or over-estimation of the properties for certain soil types may result in the misjudgment of their capacity to accept infiltrating water over large areas. It is therefore essential that textural biases are avoided, even if at the expense of introducing some random error through any data interpolation or conversion.

Other uses of soil texture

Climatic effects, such as seasonal freezing-thawing or frequent wetting and drying cycles, biological activity as well as frequent human influence, are rare in deeper soil layers that are of concern for some engineering purposes, or in layers that are already sealed. Therefore, inherent fluid retention and conductivity properties in deep, naturally textured or once-engineered soil layers will show a stronger correlation between their texture and hydraulic behavior. This is used when a soil's functionality is determined for engineering purposes, such as in the construction of earthen-dams, levees, landfills, or buildings. One of the primary soil properties of concern is the drainage capacity, whether its presence or absence is desirable. Large drainage capacity will help remove volumes of water from the surface and subsurface and contribute to good aeration, but will pose elevated pollution risks to the subsurface and groundwater resources. Soils with very little drainage capacity will serve well as 'impermeable' insulation layers, but aerobic biological processes (e.g., bio-remediation, organic decomposition processes) will be strongly hindered. One other important pool of soil properties of interest that are related to soil texture are its mechanical properties, such as precompression stress and shear-strength. Urbanization, and the general tendency of a growing amount of construction on reclaimed land is in conflict with the recent recognition of how vital our soil resources are for the future. Soil protection goals call for measures to be taken at construction sites, the extent of which depends on the knowledge of soil mechanical properties, which are primarily driven by its texture and actual moisture status.

Summary

Since particle-size distribution and soil texture are considered to be among the most fundamental soil properties, much effort has been invested since the early 1900s to measure and describe it and later to develop methods that relate it to a variety of other soil properties or characteristics like soil hydraulic properties. Yet, its representation is still problematic. I have reviewed the measurement methods predominantly in use, discussed the diversity in representing particle-size distribution as well as soil texture internationally, and argued the need to harmonize soil texture data internationally and reviewed the available options. The particle size distribution obtained from a laboratory analysis is almost always dependent on the method used, as well as the mechanical and chemical pretreatment that involves arbitrary decisions. As a result, we do not really know the absolute particle size distribution for a given soil. Nevertheless, sustained efforts are necessary to convert existing data between classification systems to avoid biases in the representation of soil texture and its subsequent applications. Despite known hindrances, the communities concerned with the representation of soil texture should work toward unifying data acquisition and subsequent classification standards. To this end, novel methods that can return quasi-continuous particle-size data may prove essential in the future.

Abstract

Soil tilth describes the friability and physical quality of a soil for crop growth. Soil tilth is an old concept yet its direct quantification remains difficult. Tilth is characterized by measuring soil properties related to soil aggregates, pore structure, mechanical resistance and organic matter, or in the field using methods such as visual evaluation of soil structure. Soil tilth is positively influenced by management that increase soil organic matter content, and negatively influenced by soil compaction. Tillage to produce tilth can have positive or negative effects over time, the latter prompting shifts to reduced or no tillage.

Key points

- Soil tilth describes the structural state and physical conditions of a soil that support plant growth
- Soil management affects soil tilth through direct and indirect effects on soil structure
- Soil organic matter is a key factor for good soil tilth
- Soil tilth was traditionally associated with plowed soils, but zero-tillage has shown that it too can produce good tilth by biological processes and weathering
- Intensive tillage can degrade tilth if it depletes carbon and structural stability
- Soil tilth is characterized by measuring properties related to soil organic matter, aggregates, soil pore structure, and soil mechanical resistance
- Direct quantification of soil tilth remains challenging

Introduction

Soil tilth is a catch-all term used initially to describe tilled seedbeds and rooting zones, but applied more recently to reduced tillage systems, including zero-tillage that are not mechanically fragmented by farmers. From the look and feel of a soil, an agronomist in the field can gain a qualitative understanding of soil tilth from its ease of fragmentation, aggregated structure and the proliferation of roots. Signs of restricted root growth near the soil surface or shoot emergence would indicate poor soil tilth.

The scientific description of soil tilth is the physical condition of soil as related to its ease of tillage, fitness as a seedbed, and its impedance to seedling emergence and root penetration (Soil Science Society of America, 1996). Ease of tillage does not apply to zero-tillage soils, but the other properties do, so the approaches to measure tilth are interchangeable across soil management practices. To some extent, “soil tilth” could be used interchangeably with “soil physical quality” in agricultural soils, although measurements are typically limited to shallow depths where the impacts on seed germination, seedling emergence and early root growth are greatest. Soil tilth is an important qualitative indicator of soil physical condition, used to describe soil structure in terms such as mellowness or friability.

Many properties of a soil will affect its tilth. Soils with poor tilth are described as appearing lifeless, resembling brick or concrete, or being cloddy (Fig. 1). If soils with poor tilth have a high percentage of sand, they will often disaggregate or separate into their primary sand-, silt-, and clay-size particles, with little or no tendency to bind together. Soils with poor tilth can also be very massive

Fig. 1 Photos showing a deep gleyic Cambisol with loamy soil texture with good (left) and poor soil tilth (right). Photos: Bettina Koster, Agridea, Switzerland.

and difficult to till, seed, or work into a suitable seedbed. Soils with medium tilth are characterized as being somewhat cloddy with a tendency to “ball up” and be “rough pulling” (i.e., requiring greater energy to break up by cultivation) when working into a seedbed. Soils with good tilth are described as being crumb-like, easy to slice (like cutting butter), and spongy. Defining the descriptive terminology for soil tilth is a challenging task for those specializing in soil management. More specifically, tilth is difficult to quantify.

Whatever the difficulties over its definition, several qualitative approaches to the evaluation of the quality of tilth in the field have been developed using rapid spade assays, such as the Visual Evaluation of Soil Structure (Guimarães et al., 2011). Moreover, quantitative information on the structural state of soil can be obtained from measurements of soil mechanical, hydraulic and gas transport properties, typically involving sampling of intact soil cores (Groenevelt et al., 1984; Dexter, 1988; Kawamoto et al., 2006). With the widespread use of X-ray computed tomography imaging in soil science, it is now possible to visualize soil tilth in 3D and directly quantify soil pore structure (Peth, 2011).

History of tilth

The term ‘soil tilth’ appeared 1800 years ago in *Cato’s Roman Farm Management* as one of the most important aspects of agriculture “What is the first principle of good agriculture? To plow well. What is the second? To plow again; and the third is to manure.” However, even though the concept of soil tilth predating modern agriculture, a clear definition has never evolved because numerous objective and subjective perceptions have conveyed different meanings. For example, a 19th century childhood story explaining the concept of soil tilth, describes how in his dying moments an old man called his children to his side to tell them that if they would dig diligently in the garden, they would find a hidden treasure. The children did so, but alas, they found no treasure of silver or gold. The subsequent harvest from this much-worked garden, however, was so large that the father’s meaning gradually dawned upon his children and they realized the wisdom of his words. A 16th century description written to provide instructions for growing peas and beans tells the farmer how to determine if the soil is ready for planting. The 1523 book entitled “*Boke of Husbandry*” states that he or she should walk on the plowed ground and “if it synges or crye, or make any noise under thy fete then it is to[o] wete to sowe; and if it make no noyse, and wyll beare thy horses, thanne sowe in the name of God.” Good soil tilth was for a long time associated with (intensive) tillage, which explains some of the resistance toward conservation tillage and zero-tillage that still exists (Karlen et al., 1990). Although good tilth may be achieved by tillage, conservation agriculture has shown that it too can produce good tilth and that over time, more intensive tillage, such as plowing, can degrade tilth if it depletes carbon and structural stability.

The value of soil tilth was described and discussed in the journal *Science* about 100 years ago (Frierson, 1921; Alexander, 1922). By 1937, Yoder had already presented a comprehensive representation of soil tilth, and described key characteristics of favorable tilth including minimum mechanical resistance for roots, adequate water infiltration and aeration, promotion of microbial activity, as well as providing bearing capacity and traction for farm implements (Yoder, 1937). These aspects and trade-offs (e.g., “fluffy” soil vs. bearing capacity) describe well the state-of-the art of desired traits of managed soil structure (Or et al., 2021). The main challenge, then and now, is the quantification of tilth and the determination of target values, optimum ranges and thresholds of soil properties associated with favorable soil tilth. Moreover, Yoder (1937) also stated that soil tilth is dynamic – the quantification of soil structure dynamics still challenges scientists today (Or et al., 2021). Among the earliest scientific articles that mention “soil tilth” are Fenton (1930) who mentioned the benefit of “good soil tilth” for the formation of pasture, and Blair (1937) and Blair and Cashen (1938) who used the shape of soil compressibility curves as a measure to quantify soil tilth. In the 1930s, several authors began to describe how climatic conditions and various soil, crop, and animal management practices affected soil tilth. In the USA, much of this research was driven by the disastrous impacts of the ‘Dust Bowl’ in the 1930s. This early research sought to describe the structure and feel of the soil tilth that formed the seedbed, generally made up of fragments produced by the action of plowing. By sieving soil samples and separating the material into different sizes, they showed how freezing, drying winds, rainfall, tillage, animal compaction and other management factors affected tilth. Eventually, soil tilth became a “blanket” term describing all the soil conditions that determine the degree of fitness of a soil as an environment for the growth and development of a crop plant (Karlen et al., 1990; Hadas, 1997). Soil structure was identified as a key factor in determining soil tilth because it is a soil property that can be rapidly altered through tillage operations and changes in environmental factors such as rainfall or temperature.

Soil tilth therefore changes over a growing season due to the intensity and timing of tillage, and changes to soil physical structure by weather, plant roots and soil organisms. Over longer time periods, soil tilth and its seasonal dynamics may also change due to management practices. As virgin grassland or forest soils are cultivated, the organic matter concentrations, base (cation) saturation, and porosity decrease, but bulk density increases. These changes reduce the granulation or tendency of the soil to form stable aggregates and gradually deteriorate soil structure. Declining soil tilth is associated with increased runoff, erosion potential, need for tillage to prepare an adequate seedbed, and fertilizer to sustain reasonable and profitable crop yields.

Soil management research through the mid-20th century focused on identifying basic properties and processes that affect soil structure and tilth (i.e., flocculation, cementing by organic and inorganic colloids, wetting and drying cycles, freezing and thawing, organic matter cycling, biological activity, and tillage). There was a drive to optimize the environmental conditions of soil for seed germination and root growth. Although tillage to produce tilth was a central to such research, the role of organic matter, root growth and microorganisms was appreciated. Over time, tilth expanded beyond plowed seedbeds as intensive tillage was degrading vulnerable soils. In the 1970’s, Brazil combatted tillage induced soil degradation by pioneering zero-tillage and conservation agriculture approaches (de Freitas and Landers, 2014). Led by innovative farmers, government researchers (e.g., Brazilian Agricultural Research Corporation - EMBRAPA) and industry partners, the new practices developed not only improved the tilth of degraded soils, but also allowed agriculture to expand onto vulnerable soils in the Cerrado. This shows awareness of the importance of not only good soil tilth, but also the impacts of physically manipulating tilth on the sustainability of soil.

Significant progress has been made in understanding many of the scientific aspects of soil structure, organic matter cycling, activities of microorganisms, and effects of various soil and crop management practices. However, with respect to the adoption of improved soil management practices, economic pressures and political forces beyond the control of most farmers often contribute to declining soil tilth. Yoder (1937) posed the question whether using soils with poor tilth or regeneration of soils was more economical – a highly topical issue of today.

Tilth of tilled and zero-tillage arable soils, and distinction from natural soil structure

Although soil tilth is primarily associated with the soil structural state induced by tillage, the widespread use and increasing adoption of zero-tillage necessitates some considerations regarding the structural state of differently managed soils (e.g., plowed, reduced tillage, zero-tillage), and distinction between natural and managed soil structure (Or et al., 2021). In this context, we may use a broader definition of soil tilth as “the soil physical condition supporting plant growth.”

Soil structure of natural and managed soil are dominated by different processes (Fig. 2). The structural state and dynamics of soil in natural ecosystems is driven by feedbacks between biological (plant growth and decay, soil organisms) and abiotic processes (soil shrink-swell induced by drying and wetting, and freeze-thaw cycles), resulting in a soil characterized by biopores, desiccation cracks and soil aggregation. In contrast, tilth of managed, tilled soil is predominantly driven by mechanical fragmentation and subsequent consolidation and coalescence of fragments created by tillage. It is important to recognize the difference between aggregates formed by natural (e.g., biology, weather) processes, and tillage-induced “aggregates”, that are the result of a fragmentation process, and therefore these are better termed “fragments.” While aggregates and fragments could look similar in size and shape, their formation processes and ecological functions are different. The (annual) soil fragmentation by tillage still dominates the (annual) “life cycle” of managed soil tilth, and tillage-induced soil fragments characterize the structure and function of soil tilth in managed, tilled systems. Natural processes are not absent in managed soil, but play a less prominent role than in natural soil. Nevertheless, it has been shown that biopores created by earthworms and roots are more dominant in reduced tillage than in plowed systems. A second distinct difference between managed and natural soil is the vegetation and hence root abundance and distribution, as well as soil carbon inputs (roots, litter). Natural systems comprise of annual and perennial plants with more or less diverse above- and below-ground features, and vegetation with typically diverse root structures (plants with different root architectures and properties,

Fig. 2 Illustration of natural soil structure (left), and managed soil structure in a zero-tillage system (middle) and under conventional tillage (right). Natural soil structure is shaped by biopore and aggregate formation from soil fauna-vegetation-climate feedbacks. Tilled topsoil structure is largely governed by mechanical fragmentation and loosening, and subsequent consolidation. Note the distinct transition from the topsoil to the subsoil in conventionally tilled soil. Zero-tillage favors higher biological activity than conventional tillage due to the lack of mechanical disturbance but lacks the vegetation diversity of natural soil ecosystems. From Or D, Keller T, and Schlesinger WH (2021) Natural and managed soil structure: On the fragile scaffolding for soil functioning. *Soil and Tillage Research* 208: 104912.

and variable rooting depths). In contrast, plants on managed (arable) soils are typically annuals, which means: the growing season is limited (between sowing and harvest), parts of the biomass production and nutrients are removed from the soil (at harvest), and the diversity of plants is low (usually one main crop at a time, some weeds but these are usually not desired and repressed). Hence, even soil in zero-tillage systems that involve minimal mechanical soil disturbance to the depth of seeding (some disturbance in unavoidable due to coulters or disks on the seeder) develops a different tilth compared with natural soil, due to the differences in vegetation and removal of harvested plant parts in managed systems, irrespective of tillage system (Or et al., 2021). In addition, periodic mechanical stresses from farm vehicles may induce disturbance (i.e., compaction) in managed soil, irrespective of tillage system.

Seasonal dynamics of soil structure in arable fields with tillage

Annually tilled soil undergoes an annual cycle of fragmentation and loosening, and subsequent consolidation (Fig. 3). The topsoil (typically 0–0.2 m depth, but regional differences and traditions exist) is mechanically fragmented and loosened during primary tillage (there is a variety of tillage implements, including the widely used moldboard plow). The fragment size distribution produced by tillage is a complex function of implement properties, velocity, and soil conditions (i.e., texture, moisture and structure), and hence, prediction of how soil fragments during tillage is not straightforward. In conventional tillage systems, the top few centimeters (the depth depends on the crop to be sown) are further fragmented and fragments are sorted (e.g., larger fragments to the top) during seedbed preparation (secondary tillage, using a harrow or similar implement). Sowing involves again some mechanical disturbance of the soil, and frequently, the seedbed is compacted by rolling, also referred to as firming, after seeding. These three steps of what is typically referred to as conventional tillage (primary tillage, secondary tillage, sowing) can be done at three different occasions, or combined into one machinery pass – there is a variety of different tillage systems and implements. Moreover, certain crops require specific tillage operations, e.g., to create ridges (e.g., potatoes). The structure of tillage-loosened topsoil is unstable, and quickly consolidates, and the discrete fragments created by tillage coalesce over time (Sandin et al., 2018). The magnitude and rate of consolidation is dependent on the amount of precipitation, frequency and intensity of wetting-drying cycles, and stability of soil. Models to predict changes of certain features of soil structure (e.g., pore size distribution) following tillage exist (Or and Ghezzehei, 2002; Roger-Estrade et al., 2009; Chandrasekhar et al., 2019), but their parameterization remains challenging.

Fig. 3 Sequence of computed tomography images illustrating consolidation of tilled soil during wetting-drying cycles. In each cycle, the samples were wetted from above (rainfall simulation, 4 h at 5 mm h⁻¹) and then drained (i.e. equilibrated) to -30 hPa matric potential during at least 5 days. Soil textural classes are silt loam (22% clay; top images), silt loam (7% clay; center) and clay (54% clay; bottom). From Sandin M, Jarvis N, and Larsbo M (2018) Consolidation and surface sealing of nine harrowed Swedish soils. *Soil & Tillage Research* 181: 82–92.

Soil organic matter and tilth

Organic matter is one of the main factors affecting soil tilth because of its role in aggregation. Studies with disturbed and undisturbed soils show that as organic matter increases, bulk density decreases and there is more space for air and water exchange. The constant addition of organic matter is one reason that virgin grassland soils generally have excellent aggregation and structure. These soil characteristics occur because in humid regions grasses replace most of their roots and top growth each year. Also, when the above ground plant material dies, it falls on the soil surface where it is decomposed or mixed into the upper part of the soil by earthworms and other soil organisms. The dead roots and plant residue provide a food source for fungal and bacterial decomposition processes leading to the formation of soil aggregates, which modify effects of soil texture with regard to water and air relationships and root penetration. Increased water-stable aggregation, annual proliferation of plant roots, and the associated wetting and drying cycles gradually develop a soil structure that is stable and with good management generally resists degradation.

The regular addition of organic materials can improve tilth by creating larger and more stable aggregates that are not easily eroded by wind or water. Organic matter, both as residue on the soil surface and as a binding agent for aggregates near the surface, strongly influences water infiltration, retention, and the potential for particle detachment and erosion. Surface residues intercept rainfall or irrigation water and dissipate the energy before the drops hit the surface, where they can detach soil particles through the splash or begin to form a surface crust by filling the voids and cracks between the aggregates with fine particles. Organic materials on the soil surface also slow the water as it flows in surface runoff, thus increasing opportunities for the water to infiltrate. Another characteristic of soils with good tilth is the presence of biopores and pore space between the water-stable aggregates. These channels greatly enhance the ability of soil to conduct water from the surface into the subsoil, where because of good root proliferation (another characteristic of good tilth) plants can subsequently use the water to support growth and development.

These impacts of organic matter, biology and weather on soil tilth affect all soils, but they are especially important under zero-tillage. In addition to fuel and labor savings, zero-tillage can increase organic matter in the top few centimeters of soil, resulting in more water-stable aggregates, and a structure that accommodates rapid plant growth with adequate root proliferation. However, if compacted layers are not loosened by tillage root growth can be restricted, so biopores provide important pathways for roots to reach subsoils.

Soil management effects on tilth

Tilth, as an indicator of the physical condition of a soil, will be strongly influenced by any soil management practice that quantitatively affects soil structure, aggregation processes, or soil organic matter cycling. Incorporating perennial crops into

extended rotations, reducing tillage intensity and frequency, or including cover crops and optimizing nutrient and water management are among the most common practices that can be used to create the desired condition.

Surface mulch from crop residues, cover crops, leaves, or other organic amendments provides both physical protection from raindrop impact and a food source for earthworms and other soil fauna, and for soil microorganisms. The surface mulch also moderates soil temperature and moisture extremes at the soil surface. If soils are left bare and exposed, surface temperatures can be very high, causing the soil to become very dry. When this occurs, earthworms and other soil insects will move deeper into the soil leaving a surface zone that contains very few active organisms. Bacteria and fungi that live in thin films of water will die or become inactive, slowing the natural process of organic matter cycling and aggregation.

A range of management options exist to improve soil tilth, mainly by increasing the action of plant roots and surface mulches, through external inputs of organic matter such as manure or compost, diversified crop rotations, cover crops and incorporating temporary leys in the rotation, or by minimizing disturbance by tillage. Information on cover crops and soil tillage can be found in other articles in the Encyclopedia. Below the specific impacts of tillage to soil tilth are described.

Tillage effects on soil tilth

Although tillage improves tilth by loosening surface soil, disrupting crusts and creating a more favorable soil-water-air environment for plants, it can also be a primary cause for the long-term deterioration of tilth. The loosening process that often has positive short-term plant production benefits may create negative long-term effects because it may increase the rate of organic matter decomposition through chemical and microbial mineralization. This occurs because previously protected organic matter is exposed by the soil fragmentation induced during tillage and subsequently used as a food source by many microorganisms. Loss of organic matter decreases aggregate stability, increasing the potential for surface crusting, poor seedling emergence, runoff, erosion, and other indicators of poor soil tilth (e.g., decreased infiltration of rainfall or irrigation water, decreased soil water retention, and decreased nutrient cycling). Tillage itself or the wheel-traffic associated with management operations can further reduce tilth by increasing compaction. Wheel-traffic reduces total pore space and frequently increases water-filled pore space leading to reduced aeration, slower nutrient cycling, and a decreased volume of soil for plant root proliferation. These processes obviously occur in fields used for crop production, but they have similar negative effects on tilth at construction sites, in forests during logging operations, on campgrounds, athletic fields, or even desert areas where off-road recreational vehicles are allowed.

Tillage has been described as being addictive for soils because of the risk of a vicious cycle that can be established. Tillage provides improvements in tilth and nutrient cycling, but there is a risk that these periods of improvement become shorter and shorter as more of the organic matter is lost through oxidation. As a result of these interactions, monitoring soil tilth may be a useful indicator of the sustainability of an agricultural system. However, whether tillage results in soil degradation and loss of organic matter is dependent, among others, on timing of tillage operations and soil and climatic conditions. The change from a plowed to a reduced or zero-tillage system results in a stratification of soil organic carbon, with higher soil organic carbon concentrations near the surface in reduced or zero-tillage soil, but impacts on total carbon stocks are often small or negligible (Meurer et al., 2018).

In situations where nitrogen was the most limiting factor, increasing nitrogen application rates and therefore crop productivity has been shown to increase soil organic matter even with moldboard plowing. Development and adoption of reduced- or zero-tillage agricultural practices have the potential to improve soil tilth even more by slowing organic matter decomposition, maintaining aggregate stability, and preserving soil structure. However, impacts of reduced and zero-tillage on soil hydraulic properties and functions are not unambiguous, with a tendency toward less macroporosity but greater pore connectivity in zero-tillage compared with conventionally tilled soils (Wardak et al., 2022). Moreover, some studies found increased risk of nutrient leaching and higher nitrous oxide emissions in zero-tillage compared with conventional tillage systems (Abdalla et al., 2013), but other studies have found the opposite (Goss et al., 1993) or inconclusive trends. The critical management practices for these systems generally focus on crop residue management, crop rotation and cover crops. Maintaining crop residue on the soil surface, permanent plant cover, and the lack of loosening through tillage reduces dispersion of the surface aggregates by rainfall or runoff. By leaving crop stubble on untilled soil or having permanent plant cover, the potential effects of wind erosion are minimized. Reducing or eliminating tillage also diminishes tillage erosion and keeps soil from being moved downhill by tillage tools.

However, reducing or eliminating tillage (i.e., zero-tillage) is no silver bullet – it can result in crop yield declines, the lack of crop residue incorporation can lead to crop disease and weed problems, and the lack of mechanical loosening can result in increasing topsoil compaction and increase nitrous oxide emissions (Soane et al., 2012; Abdalla et al., 2013; Pittelkow et al., 2015; Wardak et al., 2022). Climate, soil type and crop management (e.g., crop rotation) are factors influencing these challenges (Pittelkow et al., 2015). Soil management involves trade-offs (e.g., between food and biomass production and regulating or habitat functions), and good management aims at maximizing synergies and minimizing trade-offs between soil functions.

Evaluating soil tilth in situ

Several factors can cause soil tilth to change. Some are tillage, compaction due to wheel traffic or grazing, reconsolidation due to rainfall or irrigation, and cultivation. Qualitative observations of surface crusts, cloddiness, poor seedling emergence, ponding,

restricted plant rooting, soil organism diversity and population (especially earthworms) and increased runoff, erosion, or compaction have traditionally been used to evaluate soil tilth. Visual soil evaluation methods, e.g., the “Visual Evaluation of Soil Structure (VESS)” method (Guimarães et al., 2011) that apply robust, hierarchical field-based tests to assign scores to tilth, can be used to assess the structural state of soil, yield semi-quantitative data, and could be used to evaluate the (long-term) temporal changes of soil tilth in relation to soil management (Guimarães et al., 2017). Some of the visual evaluation methods have been designed to result in specific advice for soil management, e.g., “SOILpak” (McKenzie, 1998).

The mechanical resistance experienced by a growing plant root or tillage implement can be measured from penetration resistance. Penetration resistance is measured most precisely with a penetrometer, although a stiff wire, spade, or tile finder can also be used for a simple assessment. For precise measurements, the force required to push a rod with a cone-shaped tip through the soil to a known depth is recorded. To minimize the variation and provide the most quantitative data possible, measurements should be taken 24–48 h after rainfall or irrigation so that the soil moisture content is relatively uniform throughout the measurement zone, ideally close to field capacity. In general, if the resistance exceeds 2 MPa, root elongation is reduced by 50% and more, but this is crop-species dependent (Dexter, 1987). If the soil has good tilth, it will be fluffy, granular and separate easily along the various structural planes of weakness, but if the soil structure were massive or compacted, the tilth by definition would be considered to be quite poor.

Measurements of infiltration rates with a rainfall simulator or infiltrometers are also useful for evaluating soil tilth. These measurements are based on the time required for a known volume of water to enter the soil. If a soil has good tilth, water entry will be moderately fast for the first 5–10 cm of water. If water continues to enter at a very high rate, it could indicate the soil has no ability to retain the water or that there are cracks, crevices, fractures, root channels, earthworm holes or other macropores carrying the water away. If water enters the soil at an extremely slow rate or not at all, tilth is generally in a less desirable condition perhaps due to compaction or surface crusting. Under those conditions, rainfall and irrigation water would probably run off, increasing the potential for soil erosion and further degradation of soil tilth.

Tilth indices

Efforts to develop a tilth index were initiated to improve soil management and provide guidance for custom or prescribed tillage. The need for a tilth index was envisioned because even though an experienced person may be able to determine if a soil has good tilth by sight and feel, there was no available method to measure or quantify it. Furthermore, if soil tilth can be quantified, it may be possible to measure seasonal variation and to understand the subtle effects of soil and crop management practices such as conservation tillage or extended rotations.

The initial effort assumed that tilth of a mineral soil could be characterized by examining bulk density, strength, aggregate characteristics, organic matter content, and consistency of a soil simultaneously. Bulk density, cone index (penetration resistance or strength), and an aggregate uniformity coefficient were chosen to reflect short-term manageable soil properties. Organic matter content was chosen to reflect long-term management effects. The plasticity index was used as a measure of consistency, which reflects the relative ease with which a soil can be deformed or ruptured. This index relates to soil water properties and is strongly influenced by inherent soil characteristics (predominantly clay type and amount). These five measurements or indicators were also chosen because they can be easily measured with a routine soil test. Singh et al. (1992) proposed a tilth index based on a multiplicative combination of tilth coefficients related to bulk density, cone index, organic matter content, aggregate uniformity, and plasticity index, and proposed non-limiting, critical, and limiting values for each of these soil properties (Table 1).

Target values and optimal ranges of properties associated with desired soil tilth are presented in Table 2. However, the derivation of such values is not trivial, because optima and limiting values depend on soil texture and soil type, crop species, and soil management systems. For example, zero-tillage soils may be more compact (higher bulk density, higher mean penetration resistance) but have a better connectivity of soil pores that allows roots to proliferate despite the higher soil compactness (Wardak et al., 2022). Visual soil evaluation methods can be used to obtain information on the structural state of soil and to derive quantitative soil structure scores, as described in the previous section. Direct quantification of soil structural characteristics can be obtained by X-ray computed tomography imaging, based on intact soil cores sampled in the field (e.g., Schlüter et al., 2018). Concurrently, and with an even greater emphasis on the biological processes that affect tilth, the concepts of soil quality and more recently soil health have emerged as a strategy to quantify the effects of soil management on physical, chemical and biological properties and processes in soil (Bünemann et al., 2018; Moebius-Clune et al., 2016), as reviewed in other articles in the Encyclopedia.

Summary

The concept of soil tilth may to some extent be easier for a farmer to recognize than for a scientist to quantify. Soil tilth is used to describe soil structure in terms such as mellowness and friability, and characterizes the soil physical quality for crop growth. Traditionally, tilth has been described in many ways usually focusing on the physical condition of a soil and how it responds to tillage, functions as a seedbed, or affects seedling emergence and plant root growth and development. Tilth can be quantified in the field using methods of visual evaluation of soil structure, and based on measurements of selected soil properties on intact soil cores

Table 1 Soil measurements and corresponding coefficients developed to compute a soil tilth index for Mollisols and Alfisols in the Midwestern U.S.A.

Indicator	Description	Tilth coefficient
Bulk density	Mass per unit volume of dry soil	1.0, for $BD \leq 1.3 \text{ g cm}^{-3}$ $-1.5 + 3.87 * BD - 1.5 * BD^2$, for $1.3 \leq BD \leq 2.1 \text{ g cm}^{-3}$ 0.0, for $BD \geq 2.1 \text{ g cm}^{-3}$
Penetration resistance (cone index)	A measure of soil strength indicating ease of root penetration, plant growth, and yield	1.0, for $CI \leq 1.0 \text{ MPa}$ $1.0 - 0.002 * CI - 0.01 * CI^2$, for $1.0 \leq CI \leq 10.0 \text{ MPa}$ 0.0, for $CI \geq 10.0 \text{ MPa}$
Soil organic matter content	The organic fraction of soil excluding non-decayed plant and animal residue	1.0 for $OM \geq 50 \text{ g kg}^{-1}$ $0.59 + 0.122 * OM - 0.008 * OM^2$, for $1\% \leq OM \leq 5\%$ 0.70, for $OM \leq 1\%$
Aggregate uniformity coefficient	Shape of the grain size (aggregate) distribution curve (all of equal size gives an AUC = 1.0)	1.0, for $AUC \geq 5$ $0.348 + 0.245 * AUC - 0.023 * AUC^2$, for $2 \leq AUC \leq 5$ 0.75, for $AUC \leq 2$
Plasticity index	The difference in water content between the liquid limit and the plastic limit of a soil (cohesiveness)	1.0 for $PI \leq 150 \text{ g kg}^{-1}$ $1.0 + 0.0009 * PI - 0.00016 * PI^2$, for $15\% \leq PI \leq 40\%$ 0.80, for $PI \geq 40\%$

$$\text{Tilth Index} = CF_{(BD)} * CF_{(CI)} * CF_{(UC)} * CF_{(OM)} * CF_{(PI)}$$

Where: BD = bulk density; CI = cone index; UC = uniformity coefficient;

OM = soil organic matter; PI = plasticity index

Tilth coefficients are between 0 and 1, a tilth coefficient of 1.0 reflects non-limiting values.

and aggregates sampled in the field. Soil tilth is positively influenced by soil organic matter and negatively influenced by soil compaction, whereas tillage can have positive or negative effects. Soil management, especially tillage practices, cover crops, and crop rotations, often affects soil tilth because of its direct or indirect effect on soil organic matter. Soil scientists, ecologists, and agricultural engineers are continuing to evaluate different biological, chemical, and physical measurements or indicators that can be used individually or combined into index values to quantitatively describe tilth and to use that information to improve soil management practices, such as conservation or zero-tillage agriculture, together with the use of cover crops or more diversified and extended crop rotations.

Abstract

Crusts and seals form by the physical impact of raindrops on a soil surface. Raindrops rapidly wet and mechanically fragment aggregates on the soil surface, forming dense seal layers when fine sediment is washed into and clogs soil pores. When seal layers dry into hard crusts, long-lasting physical impacts restrict seedling emergence and alter the movement of water, energy and matter between the soil and the surface. Seal and crust layers affect important elements of landscape function, most notably by creating runoff-runon dynamics that support vegetation growth in drylands. This chapter introduces the physico-chemical basis of physical seal and crust formation, the history of conceptual and numerical models proposed to describe the properties and hydrological effects of seals and crusts, and the implications for agronomy and ecology.

Introduction

Key hydrological processes such as infiltration and evaporation are governed by the soil physical and hydraulic properties near the soil-atmosphere interface. Changes in the physical conditions of the soil surface form a compacted and hard layer—called a ‘seal’ when wet or a ‘crust’ when dry (Photo 1). Seals and crusts affect numerous hydrologic and biological processes. These changes occur frequently, dynamically during and between rainfall events, and can lead to large changes in soil physical properties. In this rapid change, physical crusts are distinct from the biological crusts found in arid or semiarid regions. Formed from microbial plant communities of cyanobacteria, green algae, lichens, mosses, and microfungi that colonize the near-surface soil, biological crusts require an establishment period of many years. In this chapter, we focus on structural seals and crusts. Natural and anthropogenic processes, such as fire or compaction, influence the structure of this upper soil layer. One of the most pervasive of these processes is the wetting of dry soils and the exposure of the soil surface to the impact of raindrops. This impact and rapid wetting can fragment large soil aggregates through a variety of physico-chemical mechanisms. The fragments produce a fine-textured and low permeability “seal” layer, which affects the flow processes in the soil profile.

Soil surface sealing can have severe agricultural, hydrological and environmental effects. Seals decrease the infiltration rate, reducing water movement to the root zone available to plants and diminishing the natural recharge of aquifers. The water that does not infiltrate forms surface runoff, increasing soil erosion. Reduced water supply and the mechanical strength of crusts inhibit seedling emergence and suppress plant growth, ultimately decreasing crop yields. In arid and semi-arid regions, soil surface sealing can induce a vicious cycle that interacts with drivers of desertification, such as overgrazing to intensify land degradation. Low vegetation cover—for example created by overgrazing—exposes the soil to rainfall, creating seals and crusts, which reduce plant vigor and growth, leaving even more of the soil area bare and exposed to rainfall. Conversely, the seal layer can be beneficial if lands are managed to maximize runoff, for example in water harvesting systems. Intriguingly, the function of many arid and semi-arid ecosystems may also depend on a mixture of sealed and unsealed soils being present in the landscape.

The formation of structural seals at the surface of bare soils exposed to the direct impact of raindrops is influenced by many factors involving soil properties, rainfall characteristics and flow conditions, as revealed by a large body of laboratory and field studies. This work has also produced several different conceptual, physical and empirical models of seal formation, seal properties, and seal effects on water and water vapor flow.

This section describes the morphology, phenomenology, and consequences of surface seal or crust layers, together with different conceptual and empirical modeling approaches to describe their properties and impacts.

What is a soil seal?

The “standard” description

Widely used descriptions state that seals or crusts “consist of two discrete and uniform layers, a 0.1 mm skin overlying a 2.0 mm washed-in layer” (McIntyre, 1958a, 1958b). In this description, the skin refers to the highly compacted, low porosity surface layer, and the washed-in layer refers to a deeper region whose properties are mostly impacted by the wash-in of fines to the pores. In practice, the thickness and properties of seal layers are highly variable—ranging from 0.1 mm up to 20.0 mm, and often the seal structure varies gradually with depth, rather than forming discrete layers (Photo 1). Light or electron microscopy, X-ray radiography or computed tomography of thin sections of the crust can all be used to measure and characterize these structural features of seals (Tackett and Pearson, 1965; Roth, 1997; Bresson et al., 2004; Garbout et al., 2014).

Why do seal layers form?

Structural seals form at the soil surface following the destruction of soil aggregates by rainfall. Two processes occur simultaneously when a raindrop collides with a bare soil surface: (1) a transfer of kinetic energy from the raindrop to the soil surface and (2) rapid imbibition of water by the soil. The transfer of energy causes mechanical changes to the soil surface, including compaction and particle detachment, while droplet splash can mobilize the fine material released by the rain impact. Simultaneously, rapid imbibition of water causes several changes to the soil. It enhances the collapse of unsaturated soil aggregates, facilitated by the sudden compression of entrapped air within the aggregates. This compression is particularly great when shrink-swell clays expand as they wet, when it can cause “explosive” destruction of aggregates, known as slaking. Wet soils also become more plastic and less cohesive, so that soil wetting increases the mechanical effects on the soil of raindrop impact.

During the early stage of seal formation, infiltration rates are often still large and there is little runoff. Under these conditions, loosened fine soil particles can be transported into the upper soil layer with infiltrating water. These fine particles fill the inter-aggregate voids in undisturbed soil, forming the seal layer (McIntyre, 1958a, 1958b). As infiltration continues, deeper aggregates are wetted, undergo further swelling and collapse, and the seal layer thickens. At the soil surface, raindrops continue to cause compaction (Bresson and Boiffin, 1990), increasing the bulk density and reducing the porosity of the seal layer.

Seal formation is a dynamic process that proceeds more slowly over time during rainfall. During the early stage of seal formation, the concentration of the fine particles in the percolating suspension is small and the open pore structure only slightly affected. The soil hydraulic conductivity allows large infiltration rates with considerable capacity to transport fine soil particles to depth. As the permeability of the surface declines, a decrease in the wash-in of fines and the rate of wetting of deeper aggregates prevents further growth of the seal layer. The saturated hydraulic conductivity of seal layers is often much smaller than the undisturbed soil. Ratios of the seal:undisturbed soil hydraulic conductivity range from 20% to as little as 0.01%. The reduction in conductivity scales with the thickness of the seal layer and the extent of compaction within it. For a given soil-rainfall system, the seal layer thickness (d_c), reaches its maximum shortly after the beginning of rainfall. It may take longer for maximum compaction of the seal layer to be reached, with some experimental studies finding that it was not attained until cumulative rainfall had reached approximately 50 mm.

Consequences of the seal layer for rainfall-runoff-infiltration partitioning

The main hydrological impact of the formation of seal layers is to reduce infiltration rates, so that rainfall is partitioned into runoff rather than infiltration (Morin and Benyamini, 1977; Romkens et al., 1986). This effect is illustrated in Fig. 1, which shows the evolution of infiltration rates over time for undisturbed soils (dotted line), for a soil on which a seal is dynamically forming (thin line), and a soil that was sealed prior to the rainfall event (thick line). Curves show a fitted infiltration model in each case.

Factors affecting seal formation

Rainfall intensity and kinetic energy play a major role in determining the seal properties and the rate of seal formation. The greater the input of kinetic energy into the soil surface via the rainfall, the more rapidly seal layers are formed and the more their properties differ from the undisturbed soil.

The formation and characteristics of the seal layer are also strongly affected by soil properties that relate to the cohesion of soil particles and stability of soil aggregates. These include (i) soil mineralogy and texture; (ii) aggregate size distribution; (iii) aggregate stability; (iv) initial bulk density; (v) initial water content distribution in the soil profile, (vi) application of phosphogypsum or polymers to the upper soil layer; (vii) slope, (viii) organic matter content; (ix) soil exchangeable sodium percentage (ESP); and (x) electrical conductivity (EC) of the applied water.

This multiplicity of soil and rainfall factors interact, so that the relationships between storm, soil and seal characteristics are complex and variable. This complexity means that direct comparison or extrapolation of experimental results is challenging. Therefore, soil scientists must rely on models to describe (i) the structure, (ii) the formation, (iii) the hydraulic properties and finally (iv) the flow of water within the seal layer.

Fig. 1 Modeled infiltration through (i) a completely formed seal (bold line), (ii) a seal under formation (thin solid line), and (iii) an undisturbed silty clay loam soil (dashed line). The measured data (open and black dots) are from Baumhardt RL (1985) *The Effect of Rainstorm Characteristics on Soil Sealing and Infiltration*. Ph.D. thesis, Mississippi State University.

Modeling soil seals

Modeling the structure of the seal layer

Conceptual models that describe the structure of the seal layer attempt to relate physical properties of the soil within the seal layer to the depth of soil within it and the characteristics of the underlying soil. The simplest such models describe the seal layer as a soil layer of a given thickness and uniform properties (e.g., Hillel and Gardner, 1969, 1970).

Mualem and Assouline (1989) suggested instead that the seal bulk density, ρ_c , should be greatest at the surface where the soil is most exposed to raindrop impact, and should then decrease exponentially with depth, h , until it approaches that of the undisturbed soil, ρ below the seal layer:

$$\rho_c(h) = \rho + \Delta\rho_o e^{-\gamma h} \quad (1)$$

where h is the depth into the soil layer, $h = 0$ at the soil surface and increases in a downward direction, $\Delta\rho_o$ is the maximum change in bulk density between the undisturbed soil and the surface of the seal layer ($h = 0$), and γ is a characteristic parameter describing the soil-rainfall interaction. γ can be related to the thickness of the seal layer (d_c) by defining this thickness through truncating the distribution at the location where changes in soil bulk density with depth are insignificant, i.e., defining that:

$$\rho_c(d_c) - \rho \leq 10^{-3} \Delta\rho_o \quad (2)$$

Giving:

$$\gamma = -\ln(10^{-3})/d_c \quad (3)$$

This theoretical model was validated against accurate measurements of soil bulk density distribution with depth (Roth, 1997; Bresson et al., 2004), as shown in Fig. 2 for a loamy silt soil. Roth (1997) suggested that a sigmoidal function (dashed line in Fig. 2) could be a more appropriate model than an exponential one, recognizing that the maximally compacted soil condition could extend slightly below the soil surface. The exponential model can readily be modified to produce a sigmoidal form by raising h in Eq. (1) to a power n (Assouline, 2004). Practically, however, both forms are similar, with the exponential and sigmoidal functions diverging only in the upper 1 mm of the soil—a region so thin that no reliable bulk density data can be obtained.

Modeling seal formation

Seal layer formation, and therefore the infiltration and runoff processes that it mediates, are dynamic and change throughout rainfall events. This dynamism means that models of the seal layer formation are needed to understand the consequences of seal layers for the fate of rainfall. Assouline and Mualem (1997) developed a dynamic model to predict the evolution of the soil seal layer over time, given the properties of rainfall (or irrigation) and the undisturbed soil.

Fig. 2 The modeled distribution with depth of the bulk density within the completely formed seal layer according to the exponential model in Eq. (1) and the sigmoidal model of Roth (1997), compared with the experimental data of Roth (1997) for a loamy silt soil. Based on Assouline S (2004) Rainfall-induced soil surface sealing a critical review of observations, conceptual models, and solutions. *Vadose Zone Journal* 3(2): 570–591.

At the soil surface, the disturbance resulting from raindrop impact and imbibition is expressed in terms of the bulk density increase relative to the undisturbed soil, $\Delta\rho_o$, as a function of rainfall intensity, I , and time of exposure to rainfall, t :

$$\Delta\rho_o(I, t) = \Delta\rho_o(1 - e^{-\xi t}) \quad (4)$$

where $\Delta\rho_o$ retains its previous definition. The term ξ captures the time-dependence of seal layer formation based on rainfall and soil properties, as defined by:

$$\xi = \frac{6\omega k I}{D_{max}\Delta\rho_o\tau} \int_0^{D_{max}} D^2 f(D, I) dD \quad (5)$$

Here, $f(D, I)$ is the raindrop size distribution, D_{max} the maximum diameter of a drop, while the parameter k links the diameter, D , of drop to its velocity (and thus kinetic energy). The variable τ represents the shear strength of the undisturbed soil, and ω , is a fitting parameter.

The measured evolution of $\Delta\rho_o$ with rainfall duration is shown in Fig. 3, with the fitted model shown in black (Augeard et al., 2008).

Modeling the seal hydraulic properties

The thin and heterogeneous nature of the soil seal layer usually precludes direct measurement of its hydraulic properties. These properties are therefore usually inferred by comparing measurements of infiltration or flow through the seal layer to models of water flow. This requires representing the seal layer hydraulic properties within the model.

The simplest hydraulic model of a seal layer is to treat it as a saturated porous medium with fixed (low) hydraulic conductivity and thickness (Hillel and Gardner, 1970; Ahuja and Swartzendruber, 1973). The limitations of this approach are that (i) it does not describe the dynamic evolution of the seal layer and its hydraulic properties, and (ii) unsaturated properties of the seal, for example its water retention curve, must be addressed when considering the drying behavior of sealed (crusted) soils.

Seal hydraulic properties can therefore be modeled using similar approaches to describing the properties of undisturbed soil (Mualem and Assouline, 1989; Baumhardt et al., 1990). For example, retaining the concept of a uniform seal layer, Baumhardt et al. (1990) represented the seal water retention curve using the Brooks and Corey (1964) model, suggesting the following approach: (i) experimentally measuring seal conductance to evaluate the saturated hydraulic conductivity assuming a given or observed seal thickness; (ii) computing the saturated water content, θ_{sc} , of the compacted seal based on the estimated saturated hydraulic conductivity and applying the Kozeny-Carman relationship (iii) estimating the water entry value of the compacted seal, h_{wevs} , using the Poiseuille equation; and (iv) determining the Brooks and Corey (1964) exponent λ_c for the seal layer graphically, assuming there is a proportional increase in the initial water content of the seal, θ_{ic} , with bulk density. As an extension to this approach, the hydraulic properties of the seal layer can be related to the bulk density profile with depth (as per Fig. 1), leading to a depth-distributed representation of the seal layer hydraulics (Fig. 4).

Mualem and Assouline (1989) have presented a different approach based on the impact of bulk density on the parameters in the van Genuchten (1980) model of the water retention curve.

Fig. 3 Evolution of the change in measured bulk density at the soil surface $\Delta\rho_o$ as a function of the duration of a rainfall event with an intensity of 30.5-mm h⁻¹ (black dots). Vertical bars correspond to the standard error of the bulk density data. Eq. (2) is fitted on $\Delta\rho_o$ data to model its change in time. Based on Augeard B, Bresson LM, Assouline S, Gaskuel C, Kao C and Vauclin M (2008) Dynamics of soil surface bulk density: Role of water table elevation and rainfall duration. *Soil Science Society of America Journal* 72: 412–423.

Fig. 4 The methodology suggested by Baumhardt (1985) for deriving the water retention curve of the seal layer. After Baumhardt RL, Romkens MJM, Whisler FD and Parlange JY (1990) Modeling infiltration into a sealing soil. *Water Resources Research* 26: 2497–2505.

Modeling water flow in a soil seal layer

Sealed soils are a special case of layered soils, and similar modeling approaches can be applied to both. The “special” aspects of the sealed soil are that seal physical and hydraulic properties are dynamic, related to those of the undisturbed soil on which the seal develops, and respond to the rainfall conditions prevailing during the seal layer formation. By linking a flow model with a seal development model such as the dynamic model of Assouline and Mualem (1997), a dynamic infiltration solution can be obtained, which allows a quantitative analysis of the soil and rainfall properties on seal formation (Assouline and Mualem, 2000).

Modeling case study—Can polymer application prevent seal layer formation

Many physical and chemical treatments are proposed to reduce the formation of soil seals, for example by manipulating the initial water content of the soil surface (Le Bissonnais and Singer, 1992), or the chemical conditions of the soil-water system (Shainberg, 1992; Levy and Rapp, 1998). Particularly promising treatments include applying small amounts of polymers to the soil surface, which can limit aggregate breakdown, reduce seal formation, increase infiltration rates and reduce runoff.

The effect of polymers on seal formation can be represented in Eq. (5) by modifying the soil shear strength parameter τ . Evaluating the sensitivity of modeled infiltration rates to τ therefore allows an evaluation of the potential outcomes of polymer treatment. Results comparing infiltration under sealed conditions and for a soil treated with 50 kg ha⁻¹ of the polymer *P-101*, which increases τ by a factor of 4, are presented in Fig. 5. As shown in Fig. 5, the modeled and observed infiltration rates agree well, demonstrating the sensitivity of seal formation, physical properties and hydrological outcomes to changes in soil shear strength. These results illustrate the potential value of simple models of soil sealing for prediction and inference, and highlight that a simple understanding of how soil amendments affects τ or K_s could be sufficient to project the hydrological effects of such treatments.

Implications

Infiltration and runoff

In most field settings, soil sealing does not occur uniformly across the landscape, but varies with heterogeneity in soil properties, soil surface cover, and local microtopographic elevation and slope. The effects of sealing on infiltration for homogeneous soils were shown in Fig. 1, and are also illustrated in the thin lines and data points (obtained from homogeneous soil column experiments of Baumhardt, 1985) in Fig. 6. This figure shows infiltration under a 120 min, 40 mm h⁻¹ storm. As expected, seal formation on homogeneous soils reduces the time of ponding (from ~40 min to ~20 min), and greatly reduces infiltration rates (Hopmans et al., 2007). The differences that arise between sealed and unsealed soils when a heterogeneous soil field is simulated, however, are less pronounced (Assouline and Mualem, 2002). In particular, (a) the time of ponding is almost identical between sealed and unsealed

Fig. 5 Simulated effect of the application of polymer P-101 on infiltration during soil sealing using the model of Assouline and Mualem (1997) and the experimental data of Ben-Hur (2001) for a loess soil. Based on Assouline S (2004) Rainfall-induced soil surface sealing a critical review of observations, conceptual models, and solutions. *Vadose Zone Journal* 3(2): 570–591.

Fig. 6 The infiltration curves simulated for a uniform (thin line) and a heterogeneous field (thick line) for the unsealed case and during seal formation, along with the corresponding measured infiltration rates in packed homogeneous soil columns (open and black dots reported by Baumhardt, 1985). In: *The Handbook of Groundwater Engineering*, JW Delleur (ed.), 2nd edn, CRC Press, Taylor and Francis Group: Boca Raton, ch. 7.

cases—reflecting the importance of low permeability soils in driving ponding before the seal layer forms; and (b) the steady state infiltration rate is greater for heterogeneous sealed soils than homogeneous sealed soils—likely reflecting a proportionally greater volume of infiltration moving through the most permeable of the heterogeneous soil properties. The modeled results assume random heterogeneity and model infiltration only—they do not therefore account for processes, such as runoff-runon, or depositional seal formation in microtopographic depressions, both of which further complicate the hydrology of sealed landscapes in field settings.

Scaling these results up further to consider runoff generation at field scales, synthetic experiments show that surface sealing—its presence and whether it is in place or forming dynamically—are the dominant factors determining runoff production from catchments where sealing could occur. As shown in Fig. 7, dynamic soil sealing increased runoff by a factor of 10, while a previously developed seal increased runoff by a factor of 20 (for a 40 mm h^{-1} , 45 min simulated rainfall event) (Assouline and Mualem, 2006). This high sensitivity suggests that (i) sealing should not be ignored in runoff assessments, and (ii) that methods to induce sealing could form part of rainwater harvesting designs—or conversely, treatments to reduce sealing could assist in mitigating flooding and erosion risks.

Fig. 7 Cumulative runoff versus time for three surface conditions in the case where 30 mm of rainfall at $I = 40 \text{ mm h}^{-1}$ are applied to a small semi-arid catchment (described in the inset) with different soil surface conditions. Based on Assouline S and Muallem Y (2006) Runoff from heterogeneous small bare catchments during soil surface sealing. *Water Resources Research* 42: W12405.

Vegetation, including agronomy and restoration

Seal and crust layers influence vegetation through altering the infiltration and evaporation of water, by presenting a layer with low hydraulic conductivity that reduces wetting and drying rates, and by predisposing the soil surface to erosion. These outcomes alter the water regime, energy regime and mechanical stresses experienced by growing vegetation, with generally negative effects on crops. For instance, in a comparison across multiple soil types and replicates, soil crusting reduced maize yields between 5% and 23% (average 15%), with the greatest yield reductions occurring under the most productive conditions (Nizami and Khan, 1991). Replanting costs associated with poorly controlled crusting in the United States in 1975 were estimated as \$US 10 million annually (\$50 million in today's values) (Edwards, 1977). Crusting is often particularly problematic for restoration practices in drylands prone to crust formation, and in high priority environments such as mine cover systems, where soil compaction is desirable to limit recharge into the covered area, but crusted soils inhibit plant establishment (Beckett et al., 2017).

Most research on crops in agronomic systems has focused on understanding the mechanical impact of crusting on seedling emergence, and on agronomic techniques for reducing crust formation. Cemented soil crusts form a barrier to emerging seedlings. Seedlings must either grow through a fracture or be able to exert enough force to break the crust. The mechanical strength of crusts, which varies with impact energy and rainfall chemistry—specifically the dispersivity of the rainwater, can vary from 0.5 MPa (low energy, low dispersivity) to 1.2 MPa (high energy, high dispersivity). The force exerted by emerging seedlings ranges from 0.15 N for alfalfa to over 4 N for maize, meaning that the pressures exerted by the seedlings are frequently too small to emerge through crusts, although results can be quite variable for a given crop type, as summarized in Table 1.

Several approaches are available to ameliorate the effects of crusting on seedling emergence. Mechanical disruption of crusts via tillage can create cracks allowing for emergence, but may also damage seedlings. Crusts can also be physically removed. Crusts can be watered to soften them and reduce their mechanical strength, although the resulting reductions in soil temperature can also impede seedling emergence. Alternatively, where crusts and cover cannot be altered, planting seeds together can assist in seedling

Table 1 Crust strength preventing emergence of several seed crops.

Crop type	Crust strength preventing emergence	References
Beans	0.03 MPa	Richards (1953)
Grain sorghum	0.2 MPa	Parker and Taylor (1965)
Pearl millet	0.02 MPa (1 seed per hole) 0.05 MPa (2 seeds per hole)	Sinha and Ghildyal (1979)
Cotton	0.03 MPa (1 seed per hole) 0.07 MPa (2 seeds per hole) 0.4 MPa	Sharma and Agarwal (1974) and Gerard (1980)

Maize	0.24 MPa (average pressure exerted by the seed) 0.7 MPa	Souty et al. (1992)

emergence from crusts—this approach is recommended in some forms of land restoration (Madsen et al., 2012) as well as agriculture. A variety of crop breeding efforts have also targeted physical and growth characteristics of seedlings that help them germinate in the presence of crusts (Anzoooman et al., 2018).

Increasingly, however, no-tillage agronomic practices are recommended to attempt to prevent the formation of the soil crust in the first place (Pareja- Sánchez et al., 2017). No-tillage residue management practices provide a canopy cover that intercepts raindrop impact and reduces evaporation, thus increasing plant-available soil water (Gabriel et al., 2021). Combining no-tillage practices that allow for integrating mulching and seeding into the untilled surface provide ways to further improve seedling germination (Xu et al., 2021). These practices protect the soil surface and limit soil drying, mitigating against crust formation. In the restoration context, new precision seeding technologies (e.g., Masarei et al., 2021) may provide similar benefits where opportunities to ameliorate the soil conditions themselves are limited.

Ecological impact of crusts

The modification of surface hydrology by soil crusts and seals influences the ecological functioning of landscapes. Crusted areas are integral to the “patchwork mosaic” concept of dryland ecosystem functioning (Aguiar and Sala, 1999), in particular the formation of “runoff-runon” units in which low infiltration capacity over crusted locations creates runoff which then infiltrates in the presence of vegetation within “runon” zones (Ludwig et al., 2005). This dynamic is shown in Fig. 8, which illustrated a situation where no infiltration occurs on crusted inter-patch areas, while within vegetated patches infiltration is enhanced relative to rainfall volumes at the upper edge of the patch (Crompton et al., 2019).

By supplying vegetated locations with water additional to that provided by precipitation alone, the runoff generated on sealed and crusted locations enables the persistence of vegetation in areas too arid to otherwise support it (Tongway and Ludwig, 1994). Infiltrating run-on also frequently contains additional nutrients, soil carbon and seeds which can fertilize and sustain the vegetation which traps them (Harman et al., 2014; Thompson et al., 2014). The recognition of the role that ‘runoff’ and ‘runon’ plays in the ‘Zai’ technique developed in Burkina Faso has led to a local farmer, Yacouba Sawadogo, to further develop it for both food crops and medicinal trees. In turn, this has contributed to countering desert encroachment and climate change (Ehlers and Goss, 2016; <https://www.youtube.com/watch?v=GYKOcq9cd1Q>; www.1080films.co.uk/yacoubamovie).

A consequence of the runoff-runon dynamic on sealed soils is that more vegetation cover is not necessarily “better” (Berghuis et al., 2020). Removing sealed areas can generate collapse of vegetation in drylands, as the plants cannot survive without the extra water. Vegetation cover that increases in response to land rehabilitation—e.g., removal of grazing pressures—may not reach 100%, but instead stabilize at a level where the water supplied by runoff provides sufficient resources to the plants. Thus, soil seals and crusts can be conceptualized as having a “dual role”—where too extensive they promote runoff which cannot be infiltrated and retained on the hillslope, creating a path to further degradation (Assouline et al., 2015). Where crusted areas are too small, by contrast, they will not supply enough water to enable full plant growth, effectively starving vegetation. This dynamic is shown in Fig. 9.

The importance of the seal layer specifically in generating these outcomes can be assessed by modeling sealed and unsealed soils on patchily vegetated hillslopes. Water content on hillslopes with and without seals, along with comparisons to field measurements, are shown in Fig. 10, which clearly illustrates the increased water content in sites where the hillslope soils were sealed (Sela et al., 2012).

Fig. 8 Infiltration following a 5 cm/h storm on crusted soils with vegetated patches with a hydraulic conductivity of 8 cm/h as simulated with a coupled Saint Venant Equation—Richards Equation model. Fig. 9 Recovering runoff plots at the Lehavim Long Term Ecological Research site in the Negev Desert, Israel on the left. Over a period of 25 years recovery from overgrazing, the vegetation cover first increased before stabilizing at approximately 25%—allowing some 75% of the hillslope to act as a runoff “catchment” on the sealed soils there. After Assouline S, Thompson SE, Chen L, Svoray T, Sela S and Katul GG (2015) The dual role of soil crusts in desertification. *Journal of Geophysical Research – Biogeosciences* **120**: 2108–2119.

Fig. 10 Average water content for all measured samples (black dots) and the corresponding simulated values for sealed (green solid line) and unsealed (brown solid line) systems. Rainfall events are depicted by the blue columns. Based on Sela S, Svoray T and Assouline S (2012) Soil water content variability at the hillslope scale: Impact of surface sealing. *Water Resources Research* **48**(3): W03522.

At the hillslope scale, predicted cumulative infiltration is greatest where both seal layers and vegetation are present, and the runoff-runon dynamic is allowed to take place (Chen et al., 2013). This is shown in Fig. 11. When vegetation cover is significant, crusts can drive desertification, but this process is potentially self-limiting. For low vegetation cover, crusts mitigate against desertification by providing water subsidy to plant communities through a runoff-runon mechanism (Assouline et al., 2015; Svoray et al., 2021).

Conclusions

Soil seal layers and crusts introduce an additional dynamic into the infiltration process. In addition to a “typical” model in which infiltration rates are reduced as soils become more saturated, in soils with sealing, infiltration rates also decline as the structure of the soil surface itself is altered by the action of rainfall. Hydrologically seals reduce infiltration, promote runoff and can promote faster, more erosive flows on their usually smooth surface. Nearly 70 years of effort have produced high quality physical models to predict these effects at point scales.

Seal layers and crusts have confounding impacts on vegetation. In agricultural systems, their mechanical strength impedes the emergence of seedlings, reducing yields and requiring farmers mechanically, chemically or agronomically adapt to their presence. The proliferation of no till agriculture and the incorporation of no till, mulching and different targeted tillage approaches have all helped to mitigate the effects of crusts on agronomy. Similar challenges arise in other settings where seeding is required, including land and mine site remediation. Here, precision seeding and agricultural engineering techniques that can overcome soil compaction and crusting offer considerable scope to improve the economic efficiency of remediation activities.

Fig. 11 Cumulative infiltration after a storm modeled on a hillslope with sealed soils (left) and sealed soils with vegetation patches present (right). The combination of sealing and vegetation leads to significantly greater cumulative infiltration than sealed bare soils especially in the vegetation patches. Based on Chen L, Sela S, Svoray T and Assouline S (2013) The role of soil-surface sealing, microtopography, and vegetation patches in rainfall-runoff processes in semiarid areas. *Water Resources Research* **49**: WR20360.

Ecologically, seal layers present a conundrum in that where too extensive they promote runoff of water, nutrients, seeds and other resources and their export from the landscape, contributing to degradation. However, landscapes without any sealed or impermeable areas force plants to depend on only the rain that falls above their roots for survival. In sufficiently dry landscapes, this can lead to seal layers being essential for the function and persistence of ecosystems. Thus, surface sealing contributes to the formation of local hydrological refugia (McLaughlin et al., 2017; Svoray et al., 2021) and form an integral physical component of functioning ecosystems.

Abstract

Soil mechanics describes the deformation of soils by mechanical stresses. Above critical stress levels, soils deform plastically so that the pore structure does not recover upon unloading. Soil moisture has a large impact on the mechanical behavior of soil. Dry soils are fairly elastic, moving toward elastoplastic behavior for moist soils, and then viscous flow for wet soils. Theories adopted from materials science and geotechnical engineering describe the response of soils to complex stresses under shear, compression or tension. However, they are insufficient to describe structurally complex, unsaturated soils typical near the surface.

Glossary

Effective stress Stress experienced in a soil due to the combined impacts of the applied mechanical stress, stress from water in the soil such as capillarity and air pressure.

Elastic A material that recovers strain completely upon removal of a mechanical stress.

Elasto-plastic A material that only partially recovers strain up the removal of a mechanical stress, with irrecoverable, plastic strain occurring beyond a critical stress level.

Mohr-Coulomb failure criterion Constitutive relationship describing the shear failure of a soil experiencing both shear and compressive stresses. It describes soil from its cohesion and internal friction between particles.

Strain Volumetric deformation of a material, often caused by an applied stress.

Stress The force acting per unit area, expressed as Pa. They can either be in shear, compression or tension.

Virgin Compression Curve Relationship between changes to void ratio or porosity with increasing compressive stress that has an initial elastic component (recompression line) with little deformation followed by greater plastic deformation (virgin compression line) above a precompression that defines the strength of the soil.

Viscous Time-dependent deformation of a material caused by its flow under a mechanical stress.

Key points

- Constitutive relationships describe the deformation (strain) of soil under mechanical stresses.
- The mechanical behavior of soil depends on soil moisture because of capillarity stresses that mechanically bond particles and the impact to plastic and viscous deformation.

- Soil pore structure is modified by mechanical deformation with both negative (e.g. compaction) and positive (fracture) impacts to the functioning of soil.
- Surface soils are structurally complex, making it difficult to apply soil mechanics theory originally developed for deeper, saturated and less structured soils.
- It is possible to modify the mechanical properties of soil by management, either by intentional fragmentation by tillage or through biological processes that bond and aggregate soil particles.

Nomenclature

ϕ	Angle of internal friction in Mohr-Coulomb failure criterion
χ	Parameter to relate matric potential (or mean hydrostatic stress) to effective stress
ν	Poisson's ratio
τ	Shear stress (kPa)
ϵ	Strain (m m^{-1})
σ	Stress (kPa)
σ_{1c}	Precompression stress (kPa)
ρ_b	Soil bulk density (kg m^{-3})
γ_{oct}	Deviatoric strain
τ_{oct}	Octahedral shear stress (kPa)
ρ_s	Soil particle density (kg m^{-3})
A	Area (m^2)
c	Cohesion parameter in Mohr-Coulomb failure criterion
E	Elastic or Young's modulus (kPa)
e	Void ratio ($\text{m}^3 \text{m}^{-3}$)
F	Force (N)
k	Sinkage parameter in the Bernstein equation of plate sinkage
K_{IC}	Fracture toughness ($\text{kPa m}^{1/2}$)
l	Length (m)
m	Constant in the Bernstein equation of plate sinkage
n	Porosity ($\text{m}^3 \text{m}^{-3}$)
p	Mean hydrostatic stress (kPa)
q	Deviatoric stress (kPa)
S_r	Degree of saturation ($\text{m}^3 \text{m}^{-3}$)
u	Deformation by stress (m)
Y	Geometry factor in fracture toughness equation

Subscripts

0	Initial condition
1, 2, 3	Subscripts for triaxial stress or strain. 1 is vertical; 2 and 3 are radial
a	Air
n	Normal direction (generally compression)
p	Pores
s	Soil
t	Shear direction
t	Solids
t	Tensile
v	Volumetric
w	Water

Introduction

Soil mechanics is a sub-discipline of soil science and geotechnical engineering that deals with the mechanical properties and processes of soils. Generally speaking, soil mechanics describes how the soil and its pore structure changes its shape or volume (or how it “deforms”) due to stresses acting on the soil. There are a wide range of soil mechanics applications in soil science, especially to predict and explain soil responses to the stresses exerted by compaction and tillage. The application of soil mechanics to soil science also extends to explore the physics of soil structure formation, shrinkage and swelling, erosion resistance, restrictions to root growth and bioturbation, and reinforcement of soil by plant roots.

Many soil mechanics concepts and methods used in soil science were initially developed to solve geotechnical engineering problems. Key issues for geotechnical engineering have some similarities to soil science. Building foundations, for instance, need to withstand the weight of buildings, whereas agricultural soils may need to withstand the weight of machinery or livestock. Evaluating geotechnical slope stability from its shear characteristics uses similar theories used by soil scientists to measure soil stability and wheel slip. Traditional geotechnical engineering, however, has focused on subsurface soils below the “dry crust.” These soils are mostly water-saturated and they are often assumed to be structureless. Describing these soils has been simplified to their component particle sizes (sand, silt, clay) and bulk density, and they tend to have mechanical properties that change little over time.

Soil scientists, however, are more interested in surface rather than subsurface soils. Surface soils are typically unsaturated, structured (i.e., have properties that are not sufficiently described in terms of particle sizes and bulk density only) and have much more dynamic properties than subsurface soils due to their greater exposure to climate and biota. This complicates understanding and a “unified theory” or “standard model” for the mechanics of unsaturated, structured surface remains elusive. Nevertheless, the basic concepts of soil mechanics such as stress, strain and deformation apply to unsaturated, structured surface soils.

This chapter provides an introduction to soil mechanics for a soil science audience. The chapter covers basic concepts taken from geotechnical engineering, and then describes methods adopted in soil science to solve practical problems involving unsaturated, structured surface soils.

A brief history of soil mechanics

Soil mechanics has been of interest for millennia, not so much as the research discipline we know today but as practical knowledge for a range of applications. Think first of early farmers who discovered the benefit of using a stick or later a plow to break up the soil for seed bed preparation, potters who took advantage of the moldability of clay, or early engineers in search of stable ground for constructing houses, roads and other structures. They were interested in either deforming and moving soil in a desired way (“soil dynamics”) or, the opposite, making sure the soil stayed in place (“soil statics”), the key problem for slope stability and foundation engineering. These early forms of soil mechanics were based on trial and error, but nevertheless effective and quite successful since the plow, pottery and principles of foundation engineering are still in use today.

It was not until the 18th century that soil mechanics was studied from a more theoretical angle, starting with the works by [Coulomb \(1776\)](#), later [Rankine \(1857\)](#) and ultimately [Terzaghi \(1925\)](#) and [Terzaghi and Peck \(1948\)](#), who is often considered the father of modern soil mechanics. Terzaghi applied the concepts of stress, strain and strength to soil as a deformable, water-saturated porous medium. Soils deform and eventually fail when exposed to increasing stress levels. The different strands of soil mechanics were brought together in what is known as Critical State Soil Mechanics (CSSM) ([Schofield and Wroth, 1968](#)), which provided a first framework that could describe the different forms of strain, deformation and failure that saturated soils undergo when exposed to external loads. Concurrently to the development of CSSM, efforts were made to describe the mechanics of soils that were not fully water-saturated, commonly termed a “unsaturated soil mechanics” ([Fredlund and Rahardjo, 1993](#); [Fredlund et al., 2012](#); [Lu and Likos, 2004](#)).

Soil scientists contributed to the development of geotechnical engineering principles, particularly on the behavior of unsaturated soils, resulting in the two disciplines starting to converge again (see e.g., [Lu and Likos, 2004](#)). Progress in material sciences and increasing computational capabilities allow for soil mechanics based on the principles of multi-physics and porous media theory, which couple mechanical, hydraulic and thermodynamic processes and properties of the soil ([Andrade and Mital, 2019](#); [de Boer, 2000](#); [Navarro et al., 2014](#)). Structured, unsaturated and biologically active surface soils can now be explored.

The concept of stress

In soil mechanics, stress is defined as a force, F , acting per unit area, A , on a body of soil. If F acts normal (i.e. perpendicular) to A , then one refers to that stress a “normal stress” σ defined as:

$$\sigma = F_n/A \quad (1)$$

If F acts parallel to A , then a body experiences a “shear stress”, τ defined as:

$$\tau = F_t/A \quad (2)$$

where F_n and F_t are the normal and shear forces, respectively. The stresses σ and τ have the units of a pressure (N/m^2 or Pa).

Because soil is a three-dimensional body, stresses can act with different magnitude and in different directions, dictated by how the applied stress is transmitted through structurally complex soils. The major stress directions experienced in soils are compression, shear and tension (Fig. 1). Compression stresses act normal to the center of the soil body and can be caused by the weight of machinery or livestock, or the weight of overburden soil. Soil compaction vulnerability can be quantified from the decrease in soil volume with increasing compression stress. Shear stresses slide a volume of soil against another volume, such as from the action of wheel slip, livestock trampling or tillage, leading to shape changes but not necessarily volume changes of the soil. Tension stresses pull the soil apart, either from an internal force such as shrinkage when the soil dries or through the action of an external force induced for example by tillage.

Tension, shear or compression stresses as depicted in Fig. 1 are ideal cases where stress only acts in one direction or within a two-dimensional plane. In practice, however, more complex stress situations occur in soils, such as the combined action of compression and shearing from wheels or livestock at the soil surface. In addition, since soils are three dimensional bodies, a combination of normal and shear stresses act in a three-dimensional space. Fig. 2 illustrates a stress situation where there is one compressive normal stress, termed σ_1 , acting vertically on a soil cylinder as well as two compressive normal stresses termed σ_2 and σ_3 acting radially on the soil cylinder. The stress state shown in Fig. 2 is called “triaxial” with σ_1 , σ_2 , and σ_3 the three principal stresses. In Fig. 2 a common assumption is made that $\sigma_2 = \sigma_3$, which further simplifies our stress considerations.

For a triaxial stress situation, there are two important stresses that define the stress state of the cylindrical body and that capture the interplay of the three principal stresses σ_1 , σ_2 , and σ_3 . The first important stress is the mean hydrostatic stress, denoted here as p , as:

$$p = \frac{\sigma_1 + \sigma_2 + \sigma_3}{3} = \frac{\sigma_1 + 2\sigma_3}{3}, \quad (3)$$

Fig. 1 Normal and shear stresses acting on a two-dimensional body of soil.

Fig. 2 Principal stresses σ_1 , σ_2 , and σ_3 acting on a cylindrical body of soil.

assuming $\sigma_2 = \sigma_3$ as shown in Fig. 2. The hydrostatic stress in a soil is similar to the pressure found inside of a column of a liquid such as water (therefore the name “hydrostatic” stress). The second important stress is the octahedral shear stress, denoted τ_{oct} :

$$\tau_{oct} = \frac{\sqrt{2}}{3}(\sigma_1 - \sigma_3) \quad (4)$$

Some soil mechanics models use the deviatoric stress, q , instead of the octahedral shear stress, τ_{oct} , with q defined as:

$$q = \sigma_1 - \sigma_3. \quad (5)$$

In simple terms, the triaxial stress state of a cylindrical body of soil can be described by the mean hydrostatic stress, p , and either the octahedral stress, τ_{oct} , or the deviatoric stress q . This is important because the mean hydrostatic stress controls volume changes (such as soil compaction) and the deviatoric (or octahedral) stress controls shape changes of the soil (such as breaking up soil by tillage, movement of an unstable slope or debris flow). In other words, shear deformation of the soil is caused by the difference between the principal stresses, whereas volume changes (such as compaction) are caused by the average of the three principal stresses.

Total versus effective stress

Soil is a three-phase system, consisting of solid particles, and pores filled with variable amounts of air and water depending on water content. This further complicates the mechanical characterization of the soil as stress can occur in each of these three phases. The total stress that the soil undergoes can be divided between solid, water and air stresses using the concept of effective stress. The mean hydrostatic stress, p , as given in Eq. (3), is an effective stress made up of the stress acting on the solids, p_t , pore water, p_w and pore air, p_a , simply defined by the sum of these stresses:

$$p = p_t + (p_w + p_a), \quad (6)$$

where p_a is often zero as it is irrelevant in saturated soil and rapidly equilibrates with atmospheric pressure in unsaturated soils. Stresses in the soil caused by external loads such as the weight of a building or a vehicle are total stresses, not effective stresses, and the effective stresses they cause depend on the water and air pressure. This means that part of the total stress, p_t , in the soil caused by a load applied on the soil surface can be offset by the pore water pressure, p_w . Hence, the effective stress, p , may be small or even zero and, therefore, little to no strain or deformation will occur even though the soil surface is loaded. If the load at the soil surface is applied long enough, then the pore water pressure may dissipate with time through drainage, causing the effective stress to increase and some slow but steady soil deformation under the load called “consolidation.” Consolidation is of great importance in geotechnical engineering due to foundations (e.g., Wesley, 2010).

For unsaturated soil, Eq. (6) still holds but needs to be extended. Under unsaturated conditions, p_w changes from positive to negative pressure or “tension.” Consequently, the effective stress acting on unsaturated soil is no longer smaller (or equal) to the total stress but can be greater than the total stress. One example of this phenomena is that moist, unsaturated sand is generally “firmer” than saturated, wet sand because of the “sandcastle effect.” A sandcastle built with wet, water saturated sand collapses, but moist, unsaturated sand holds together. If the sand dries more, water holding together the particles is lost and the sand gets weaker. The strength of moist sand is caused by capillary forces induced by the interface between water and air within the pores of the sand, affected by p_w , which is analogous to water potential.

In an unsaturated soil, p_w acts only in water-filled and not air-filled pores. This can be accommodated in Eq. (6) by a factor, χ that is related to the amount of water:

$$p = p_t - \chi p_w \quad (7)$$

known as Bishop’s effective stress equation (Bishop, 1959). Although χ depends on the saturation degree, S_r , or the moisture content, θ , of soil, it is an empirical parameter derived from mechanical tests. For fully water saturated soil, $\chi = 1$, simplifying Eq. (7) for unsaturated soil into Eq. (6) for saturated soil. For air-dry soil, χ is assumed to equal to 0, so the effective mean hydrostatic stress, p , is equal to the total mean hydrostatic stress, p_t . In between these two moisture extremes, $0 < \chi < 1$.

If an applied stress is much greater than the water potential of the soil, a total rather than an effective stress approach can be used as χp_w will have a small impact. To illustrate this, let’s assume the total stress in the soil under a heavy load is 200 kPa. Let’s also assume that soil below the load is unsaturated with a water content around field capacity, which is equivalent to a water pressure in the soil pores around –10 kPa. For these conditions, according to Eq. (7), the effective mean hydrostatic stress, p , will be less than 5% higher than the total mean hydrostatic stress, p_t , because we know that for unsaturated conditions $\chi < 1$, which means that the absolute value of χp_w is less than 10 kPa. Therefore, with the total stress approach, it can be assumed that the total stress in the soil is approximately equal to the effective stress. When using the total stress approach, it is important to consider that the material properties of the soil become moisture-dependent (Berli et al., 2015).

The concept of strain

When a body of soil is subjected to sufficiently large external forces, it deforms. The ratio of these deformations to the original dimensions of the body are known as ‘strain.’ As a simple one-dimensional example, let’s assume we have a slender rod of length

Fig. 3 A slender rod undergoing a compressive force, F , leading to compressive deformation, u , and compressive strain, ε .

l that is subjected to a uniaxial compressive force, F (Fig. 3). Due to the force, the length of the rod will decrease by a certain amount of compressive deformation, u . The compressive strain, ε , of the rod can be then defined as:

$$\varepsilon = u/l \quad (8)$$

This concept of one-dimensional strain can be extended to three dimensions for a cylindrical body of soil undergoing triaxial stresses as shown in Fig. 2. For each of the three principal stresses, σ_1 , σ_2 , and σ_3 , a corresponding principal strain ε_1 , ε_2 , and ε_3 , can be defined to represent the strains of the cylindrical body as a reaction to the corresponding principal stresses, σ_1 , σ_2 , and σ_3 .

Similar to the mean hydrostatic and deviatoric stresses, one can define a corresponding volumetric strain, ε_v , shear strain, ε_s , and deviatoric strain, γ_{oct} , respectively, given as:

$$\varepsilon_v = \varepsilon_1 + \varepsilon_2 + \varepsilon_3 \quad (9)$$

$$\varepsilon_s = \frac{2}{3}(\varepsilon_1 - \varepsilon_3) \quad (10)$$

$$\gamma_{oct} = \frac{\sqrt{2}}{3}(\varepsilon_1 - \varepsilon_3) \quad (11)$$

assuming $\sigma_2 = \sigma_3$ and, hence, $\varepsilon_2 = \varepsilon_3$. The volumetric strain, ε_v , is important because it is a measure of soil compaction. Changes in void ratio, Δe , of the soil can be used to calculate ε_v by:

$$\varepsilon_v = -\frac{\Delta e}{1 + e_0} \quad (12)$$

with e_0 the initial void ratio of the soil. The void ratio of the soil is defined as the ratio of total pore space of a soil, V_p , to the total volume of the solid space of the soil, V_s , according to:

$$e = \frac{V_p}{V_s} \quad (13)$$

Note the negative sign in Eq. (12) owing to the sign convention that treats compressive strains (and stresses) as positive. Void ratio is commonly used in soil mechanics because the denominator, V_s , does not change with strain. This is different from other areas of soil science where porosity or bulk density are used to describe the volumetric strain, ε_v . All these volumetric strain parameters are related. Void ratio, for example, can be easily calculated from other soil physical properties such as porosity, n , by:

$$e = \frac{n}{1 - n} \quad (14)$$

Or dry bulk density, ρ_b :

$$e = \frac{\rho_b}{\rho_s} - 1 \quad (15)$$

with ρ_s the particle density of the soil.

Eqs. (9) to (11) provide the foundation to calculate strain (and by extension deformation, if needed) of a body of soil undergoing triaxial stress conditions as given by Eqs. (3) to (5). What is still missing are the constitutive relationships to describe how stress and strain of the soil are related, one of the key tasks of soil mechanics. The constitutive relationships depend on the texture, moisture and structure of the soil.

Constitutive relationships for soil materials

Soil constitutive relationships describe how stress and strain are related, why different soils respond differently to the same level of stress or why the soil deforms differently depending on the level of applied stress. At low levels of stress, the corresponding strains are small and can disappear once the stress is removed. This type of stress-strain behavior is called “elastic”, like a metal spring that bounces back to its original size and shape once the stress is released. Above a yield stress, strain is irrecoverable after the stress has been removed. With increasing stress, more irrecoverable strain occurs. This type of stress-strain behavior is called “elasto-plastic.” When the stress level on the soil is further increased, the body of soil “fails.” Soil failure can be desired, such as in the case of plowing where the compacted surface soil is broken up into looser clods by shear failure of the soil at the plowshare. Soil failure, however, is often undesired, such as a failing foundation under a building, slope failure of a dam or a landslide, sometimes with devastating consequences for life and property.

Therefore, the strain response of soil to an applied stress can be elastic (recoverable), plastic (irrecoverable) or failure, depending on the mechanical properties of the soil and the amount of stress that is applied. Above a yield stress, plastic deformation occurs. Above the failure stress, failure occurs. Fig. 5 shows these various forms of strain responses of soil to applied stress, expressed in stress-strain diagrams. Linear-elastic stress-strain behavior shown in Fig. 5A is an ideal case where there is a linear increase in strain with increasing stress, with complete recovery of strain when the stress is removed. Soil rarely exhibits linear-elastic behavior (Fig. 5A), so a nonlinear-elastic constitutive relationship (Fig. 5B) describes soil loading behavior along a particular loading or unloading path.

Rigid-perfectly plastic (Fig. 5C) and elastic-perfectly plastic (Fig. 5D) models, respectively, are sometimes used in soil mechanics, particularly in limit equilibrium analysis to assess at what level of stress a soil fails. Fig. 5E represents the typical stress-strain behavior of soil under triaxial compression, described earlier in Figs. 2 and 4. Stress in Fig. 5E would correspond to the mean

Fig. 4 Principle strains, ϵ_1 , ϵ_2 , and ϵ_3 of a cylindrical soil sample undergoing principle stresses σ_1 , σ_2 , and σ_3 . ϵ_1 , ϵ_2 , and ϵ_3 are defined in terms of the dimensional changes, l_1 , l_2 , l_3 of the cylindrical samples in the three principle directions relative to the original dimensions, l_{01} , l_{02} , l_{03} . Swiss Federal Institute of Technology (ETH), Zurich.

Fig. 5 Idealized stress–strain curves for solid materials: (A) linear-elastic; (B) nonlinear elastic; (C) rigid-perfectly plastic; (D) elastic-perfectly plastic; (E) and elastoplastic behavior.

hydrostatic stress given in Eq. (5) and strain to the volumetric strain provided by Eq. (9). In this example, a cylindrical soil specimen as shown in Figs. 2 and 4 exhibits elastic behavior until the applied stress reaches the yield stress (point A) on the soil stress–strain curve. The specimen will no longer deform elastically but will start to deform plastically if further stress is applied from point A to point B. The other letters indicate cycles of loading and unloading. These follow a different path due to plastic deformation, with some elastic recovery as seen from C–D or G–H in Fig. 5E. When loaded again the stronger, plastically deformed soil responds differently until the applied stress reaches the maximum stress applied in the previous loading cycle, where the stress–strain relationship returns to the same path as the initially unloaded specimen.

Beyond point F in Fig. 5E mechanical behavior depends on how the mean hydrostatic stress (Eq. 3) and the deviatoric stress (Eq. 5) evolve with increasing stress level. If primarily the mean hydrostatic stress, p , increases with increasing stress level while the deviatoric stress, q , remains low (what “low deviatoric stress” exactly means will be further elaborated in the section on failure criteria), then the density of the soil specimen will increase (or “harden”, as it is usually referred to in material science). The extreme case occurs if all three principal stresses are of the same magnitude and the deviatoric stress equals zero. Under these hydrostatic stress conditions, the soil specimen undergoes pure compaction, and the soil will become denser and denser with increasing applied stress. If, however, q in the soil specimen is high (again, “high deviatoric” will be further elaborated in the section on failure criteria), then the density of the soil specimen will decrease (or “loosen”) with increasing applied stress and the specimen will eventually “fail” when the deviatoric stress meets the failure criteria. In a nutshell, the fate of the cylindrical soil specimen very much depends on the relationship between p and q .

The stress-strain relationships shown in Fig. 5E are helpful to understand the different stages of stress-strain behavior a soil undergoes with increasing stress level. It is important to remember, however, that the curves shown in Fig. 5 are primarily conceptual models. When dealing with surface rather than subsurface soils, the mechanical response may be more complex due to the impacts of soil structure. Moreover, these curves assume that the relationship between stress and strain does not depend on time.

Many stresses acting at the soil surface, however, are very dynamic. These can be due to rapid imposed stresses, such as from a moving wheel or livestock, or slow processes such as the gradual slumping of a seedbed. Under a rapid dynamic stress, a delayed, viscous strain can occur, so the soil may deform very little even if exposed to stresses much higher than yield stress. The viscous response of the soil to stress also explains why multiple exposure of the soil to the same stress, such as by repeated wheeling by machinery, may result in increasing strain, even though the individual stress event is short. The viscous deformations that each pass causes are additive so after a sufficient amount of passes a sizeable amount of deformation can occur, even though the deformation from a single pass was small.

Viscous processes also have a large impact on the coalescence of seedbeds, and the gradual elongation of plant roots through soil. The time-dependency of soil stress-strain relationships has been largely neglected in soil science, only addressed in a few studies (Berli et al., 2006; Berli and Or, 2006; Ghezzehei and Or, 2001; Vyalov, 1986) despite its great importance for the mechanics of surface soils. Mechanical behavior can be described by “elasto-viscoplastic” stress-strain relationships where the elastic deformation is (almost) instantaneous, but the plastic deformation, at a sufficiently high stress level such as higher than yield stress, takes time to develop. For instance, pottery clay is an elasto-viscoplastic material, so it takes time to mold the lump of clay into a new shape even if a good amount of stress is applied to the lump.

Linear-elastic soil behavior

Even though linear elasticity is rarely observed in natural soils, many models and descriptions of soil mechanical processes assume linear-elastic behavior (Fig. 5A). Early theories of material mechanics assumed linear elasticity, and the simple stress-strain relationship makes it an ideal starting point for an introduction to soil mechanics.

Eqs. (1) and (6) define stress and strain for a one-dimensional (in soil mechanics also called “uniaxial”) compressive stress as shown in Fig. 1. For a linear elastic material, the following simple linear equation relates compressive stress, σ , with strain, ϵ :

$$\sigma = E\epsilon \quad (16)$$

with E the elastic or Young's modulus of the material. For a three-dimensional body, as shown in Figs. 2 and 4, undergoing a triaxial stress with $\sigma_1 > \sigma_2 = \sigma_3$, the axial compression of the specimen leads to a radial expansion of the specimen (Fig. 4). This means that the cylinder becomes “shorter” and “thicker” under triaxial stresses. The relationship between axial, ϵ_1 , and radial strain, ϵ_3 , assuming $\epsilon_2 = \epsilon_3$, is defined by the Poisson's ratio of the material, ν , given as:

$$\nu = -\frac{\epsilon_3}{\epsilon_1} \quad (17)$$

Note the minus sign in Eq. (15) indicating that if the compressive strain ϵ_1 is positive, according to the sign convention in soil mechanics, the “expansive strain” ϵ_3 has a negative value. With a uniform, linear-elastic body, two material properties, E and ν , fully describe the stress-strain behavior of the body. For a triaxial stress state, Eqs. (16) and (17) allow the relating of p and ϵ_v from Eqs. (3) and (12), as well as q and ϵ_s from Eqs. (5) and (10) according to:

$$p = \frac{E}{3(1-2\nu)}\epsilon_v \quad (18)$$

$$q = 3 \left[\frac{E}{2(1+\nu)} \right] \epsilon_s \quad (19)$$

So, under the assumption that soil can be described as a uniform, linear elastic body undergoing triaxial stress, all of soil mechanics can be described by Eqs. (18) and (19). More complex relationships are needed to describe elasto-plastic behavior, as introduced in the next section.

Elastoplastic soil behavior

This section outlines elastoplastic behavior of soil under compressive stresses, as illustrated in Fig. 5E. Mohr-Coulomb failure criterion is introduced to describe mechanical conditions when stresses are adequate to cause failure.

Elastoplastic soil behavior under compressive stresses

Testing of soil compressive stress can use a triaxial device, as illustrated in Fig. 4, or confined compression tests where the sample is restricted from moving axially, so $\epsilon_2 = \epsilon_3 = 0$ and only the axial strain, ϵ_1 , remains. Confined uniaxial compression tests are popular

to study the mechanics of surface soils because they are simpler to run than full triaxial tests and, for most practical purposes, provide sufficient information about the elasto-plastic behavior. Fig. 6 illustrates the idealized behavior of a soil sample under confined compression. Here the axes are flipped, with axial strain or its equivalence as void ratio (Eq. 12) on the y axis, and the logarithm of the applied compressive stress on the x axis. Plotting this way is the convention in soil mechanics. Two straight dashed lines approximate two stages of mechanical behavior. An initial recompression curve is the elastic component where little deformation occurs. On unloading the axial strain would recover and no compaction would occur, such as from light traffic on dry soils. Greater deformation occurs beyond a precompression stress, σ_{1c} , producing irrecoverable plastic deformation that follows the virgin compression line. The intersection between these two lines is approximately σ_{1c} .

The precompression stress is similar to yield stress. It depends on the stress history of the soil, so it increases when soils are damaged by compaction, but it can also partially recover over time through weathering or tillage. Many interpret precompression stress as the highest amount of axial stress that the specimen has experienced, so it is commonly used as an indicator of soil compaction history and damage. Fig. 6 illustrates the simple Casagrande approach to approximate σ_{1c} from the intersection between straight lines plotted as recompression and virgin compression curves, but other approaches have been proposed to derive σ_{1c} from the shape of the entire curve. At very high stresses, little pore space remains so axial deformation deviates from the virgin compression curve and eventually ceases. This is generally beyond the stresses that are typically applied to soils, so ignored in analysis. With real soil data, recompression and virgin compression curves may not be as obvious as Fig. 6 suggests.

Fig. 7 shows examples of measured and modeled axial strain (strain expressed in terms of void ratio, see Eq. 13) versus axial stress curves. These were carried out on undisturbed, unsaturated, structured silt-loam soil collected from three different depth of 12 cm 52 cm and 72 cm below the soil surface (Berli, 2001; Berli et al., 2015). Symbols represent measured and lines modeled stress-strain values using the approach by Casini (2012). The modeled compression curves are bi-linear and therefore similar to the idealized stress-strain curve shown in Fig. 6, but with a less distinct intersection between the recompression and virgin compression lines. The soils were initially equilibrated to different water suctions, which because of effective stress, shift behavior depending on the impacts to capillary cohesion and distribution water affecting χ (Eq. 7).

Soil failure - shear

Whereas a compressive stress (Fig. 1) in confined conditions can decrease pore space, depending on the directions of applied stresses and confining conditions from surrounding soil, a soil may deform and ultimately fail. Soil failure generally occurs from a combination of stresses applied to soils in different directions. This section introduces Mohr-Coulomb theory as an example of a simple failure criterion frequently used in soil mechanics. Mohr-Coulomb focuses on the internal friction within the soil mass as the main failure criterion by defining the maximum amount of shear stress, τ_{max} , a soil specimen can withstand before falling apart. For a triaxial stress situation with principal stresses σ_1 , σ_2 , σ_3 and $\sigma_2 = \sigma_3$ as defined in Fig. 2, the Mohr-Coulomb failure criterion can be written as follow:

$$\tau_{max} = c + \sigma_n \tan(\phi) \quad (20)$$

with

$$\sigma_n = \frac{\sigma_1 + \sigma_3}{2} \quad (21)$$

the normal stress on the failure plane, τ_{max} the maximum shear stress on the failure plane, c the cohesion and ϕ the angle of internal friction of the soil, respectively. Fig. 8 is a graphical representation of the Mohr-Coulomb failure line superimposed on a typical Mohr circle defined by the principal stresses σ_1 and σ_3 .

Fig. 6 Idealized stress-strain curve for an elastoplastic soil undergoing confined uniaxial compression. The transition from (elastic) recompression to (plastic) virgin compression is characterized by the precompression stress, σ_{1c} .

Fig. 7 Measured (symbols) and modeled (lines) of effective axial stress vs. void ratio curves employing the model by Casini (2012) for specimen of structured, unsaturated agricultural soil collected from depths of (A) 12 cm, (B) 52 cm, and (C) 72 cm. Each symbol represents the arithmetic mean of four to nine individual measurements (Berti et al., 2015 Fig. 6). s_0 indicating the initial suctions of the soil specimen.

Fig. 8 Mohr-Coulomb failure criterion for soil showing the relationship between shear stress, τ and normal stress, σ_n , for a soil with cohesion, c , and angle of internal friction, ϕ .

Fig. 8 as well as Eqs. (20) and (21) imply that if the Mohr circle defined by the principal stresses σ_1 and σ_3 touches the Coulomb failure line, the soil specimen will fail. If the Mohr circle does not touch the Coulomb failure line, however, the principal stresses σ_1 and σ_3 do not cause the soil specimen to fail. The Mohr-Coulomb failure criterion tells us that there are three main parameters that define whether a soil fails or not. First there are the two principal stresses σ_1 and σ_3 . One can see from Eqn. (20) that with increasing normal (or compressive) stress, σ_n , also the maximum shear stress, τ_{max} , increases. i.e., the greater the normal stress, σ_n ,

the greater the shear stress the soil can withstand without failure. The most extreme case in this respect occurs if $\sigma_1 = \sigma_3$, i.e., all three principal stresses have the same magnitude and equal to the mean hydrostatic stress, p . For $\sigma_1 = \sigma_3 = p$, the Mohr circle shrinks to a single point and the Mohr-Coulomb failure criterion tells us that under these (hydrostatic) stress conditions no failure can occur.

The other extreme stress situation occurs if the axial stress, σ_1 , has a non-zero positive value but the radial stress component, σ_3 , becomes zero. This stress situation occurs in a uniaxial compression test. Fig. 9 shows the Mohr-Coulomb diagram with $\sigma_3 = 0$ for a soil with the same cohesion, c , and angle of internal friction, ϕ , as shown in Fig. 8. By comparing the stress values, σ_1 , from Figs. 8 and 9, for $\sigma_3 = 0$ the stress values σ_1 at failure are considerably smaller than for $\sigma_3 > 0$. The key parameter to assess failure is the difference between σ_1 and σ_3 , or what we defined in Eqn. (5) as the deviatoric stress, q . In the soil mechanics literature, other more advanced failure criteria are discussed, which are typically formulated in terms of the stresses of p and q (see e.g., Critical State Soil Mechanics; (Schofield and Wroth, 1968)). However, a comprehensive discussion of failure criterion is beyond the scope of this chapter.

Besides the stress state given by the principal stresses σ_1 and σ_3 , the two soil properties cohesion, c , and angle of internal friction, ϕ , play an important role in assessing soil failure. These depend on soil properties and from a practical standpoint they can be modified by soil management and amendments. Cohesion is a measure of how strongly the soil particles “stick” together, whereas the angle of internal friction is a measure of how hard it is to move soil particle relative to each other. Cohesion and angle of internal friction depend on the type of soil. Clays, for example, generally have high cohesion but a low angle of internal friction, whereas (dry) sand or gravel are examples of soils that exert high internal friction angles but have no cohesion. As illustrated in Figs. 8 and 9, as well as Eq. (20), greater values of c and ϕ result in greater maximum shear stress for a given normal stress. Note that c is independent of σ_n , meaning that a soil can have some cohesion without being stressed. To go back to the pottery example used earlier on, pottery clay sticks together (“has cohesion”) if it is not stressed.

Soil moisture, via effective stress, can also contribute to cohesion, even in sands that have little particle bonding when dry. Recall the sand castle effect where “at the right water content” the sand grains are held together by capillary forces, being responsible for what is sometime referred to as “apparent cohesion.” This apparent cohesion depends on the moisture content and disappears if the sand gets too wet or dries out. For soft surface soils, as found in many agricultural or forestry applications, cohesion plays an important role and primarily determines whether a soil fails. The angle of internal friction, however, plays less of a role, unless the applied stresses are considerably higher than the cohesion. Examples include under the wheel of a heavy vehicle or the hoof of an animal that is sinking into soft soil. This results in $\sigma_3 > 0$ but also $\sigma_1 \gg \sigma_3$ and, hence, according to Eq. (20) the angle of internal friction starts controlling the maximum shear stress.

Mohr-Coulomb characteristics can be measured by a triaxial test or a simpler to conduct direct shear test. In the direct shear test, a soil sample is placed in a split block or ring, with one half moved across the other to produce a defined shear failure zone. Weights are placed on the soil to control σ_n .

Soil failure - fracture

Depending on the direction of the applied stress and the plasticity of a soil, failure can be dominated by fracture. This occurs from the extension of pre-existing cracks in the soil. As applied stresses cannot pass across these cracks, the stresses are concentrated at the tips, greatly reducing the stress required to cause failure (Fig. 10). The weakest state of a soil is fracture from tensile stresses, which can occur from soil shrinkage upon drying. Fracture can also occur from shear and compressive stresses, as they can open up the tips of cracks, causing them to elongate under tension (Fig. 10).

Fracture by crack elongation in soils dominates in dry, brittle conditions. Often linear elastic behavior is assumed, with the failure stress under tension, σ_T calculated with fracture mechanics by:

Fig. 9 Mohr-Coulomb failure criterion for $\sigma_3 = 0$ and a soil with same cohesion, c , and angle of internal friction, ϕ , as shown in Fig. 8.

Fig. 10 Concentration of stress at the tip of cracks showing examples of direct tension of a half crack (left) and indirect tension caused by crack opening from a compressive stress on a disk (right). The gray arrows are the direction of the applied stress, with thinner lines showing stress transmission in the specimen.

$$\sigma_T = \frac{K_{IC}}{Y\sqrt{c}} \quad (22)$$

where K_{IC} is the fracture toughness, c is the length of the crack and Y is a geometry factor to account for the shapes of the sample and crack (Hallett and Newson, 2005). The parameter K_{IC} is independent of crack size, depending on the bond strength of soil particles at the crack tip.

Measuring K_{IC} of soil requires remolded specimens with controlled crack lengths and specific geometries to apply a tensile stress at the crack tip. In intact, structured soil it is impossible to measure. Here the transmission of stress and its concentration at crack tips will be affected by interacting, geometrically complex crack networks. The disk-shaped specimen illustrated on the right of Fig. 10 shows opening of a crack by a compressive stress, resulting in tensile strains developing at the crack tip. This is an idealized image of indirect tension stresses resulting at crack tips, which can occur regardless of the direction of the applied stress (Fig. 1).

As described previously, soils are not linear elastic materials, even when dry. Eq. (22) can be adapted to account for elasto-plastic behavior with nonlinear fracture mechanics, but this requires more complex analysis and testing.

Measuring soil mechanical behavior in the field

To use soil mechanics for practical applications, one needs to know the mechanical properties of a soil. Previous sections described uniaxial compression, triaxial compression and direct shear tests that are conducted in the laboratory. Cone penetrometers, shear vanes and sinkage plates are three examples of field testing equipment developed to measure the strength and compressibility of soils for tillage, traction, and soil-compaction studies. These devices provide soil-strength parameters that tend to depend on the geometry of the test device and the type of loading applied. Moreover, these soil parameters often do not represent any single soil property, but are usually functions of several fundamental engineering properties of soil. Therefore, soil parameters obtained using these devices (e.g., penetrometers, shear-vane devices, and shear graphs) are often called 'composite soil parameters.' There are also various techniques used to determine soil stickiness, shatter resistance, and cutting resistance. The cone penetrometer is well-known among these devices because it is a simple device that is very easy to use. Shear-vane devices and shear graphs have been used to obtain soil shear and sinkage parameters. They are useful in predicting the tractive ability of wheels and tracks using a semiempirical approach.

Cone penetrometer

Perhaps the most widely used device to measure soil strength in the field is the cone penetrometer. Although the cone penetrometer was developed to determine the mobility of off-road vehicles, it has been used to predict traction, draft requirements of tillage implements, and to quantify soil strength to indicate soil-compaction level and impedance to root growth. The most common form of this device consists of a polished steel cone, which is pushed against the soil and then the force of penetration is measured. The American Society of Agricultural Engineers (ASAE) standard (S313.3) describes the geometry of a standard cone penetrometer, whereas a second standard (EP542) outlines the proper procedure for using this device.

Since the force needed to penetrate the soil is related to the geometry of the device, a cone with a base diameter of 20.27 mm and an apex angle of 30° is selected as the standard (Fig. 11). For harder soil conditions, a smaller cone with a base diameter of 12.83 mm is used. A second key variable that influences the force of penetration is the penetration rate. ASAE Standard EP542

Fig. 11 Standard cone penetrometer of the American Society of Agricultural Engineers.

recommends a quasistatic rate of 1.83 m min^{-1} . Although it is difficult to control the insertion rate with handheld devices, hydraulically or electrically operated devices can be designed to operate at this standard speed. Force is usually measured using a load-sensing mechanism such as a load cell. Newer devices often include a depth-measuring sensor such as a potentiometer so that a soil penetration resistance profile can be obtained. The penetration resistance force is expressed as the cone index, which is the ratio of the force to the base area of the cone. The soil cone index value obtained using a soil cone penetrometer is a composite value that depends on soil texture, bulk density, and moisture content. In terms of engineering properties of soil, it depends on cohesion, soil internal angle of friction, soil metal friction, and adhesion.

One of the main concerns with the use of cone index to represent soil strength is its variability, especially in dry and cloddy conditions. ASAE standard EP542 recommends that in a given location at least 20 measurements be taken at a water content near to the field capacity of soil to obtain a representative measure of soil strength. With the advent of precision agriculture and the potential role of soil compaction in limiting water infiltration, drainage, and root growth, there is an increased interest in the cone penetrometer as a soil-strength mapping tool. Consequently, fully automated cone penetrometers with global positioning systems (GPS) to provide geographic position data are now commercially available.

Soil sinkage

Cone penetrometers are inadequate to measure soil characteristics relevant to tractive ability of wheels and tracks, so sinkage devices can be used. Soil sinkage devices consist of either circular or rectangular plates that are pushed against soil, and their load deformation characteristics are recorded (Fig. 12). The Bernstein equation is often used to relate applied pressure, p_s , to soil deformation, z as:

$$p_s = kzm, \quad (23)$$

where m is a constant and k is the sinkage parameter dependent on soil cohesion, angle of internal friction, and plate dimensions. Plate sinkage relationships have been used to model rolling resistances of wheels and tracks.

Soil shear

Shear characteristics of soil such as cohesion and angle of internal friction have been used to model the tractive ability of wheels and tracks, soil fragmentation by tillage tools, soil stability and the mechanical resistance to root growth. In soil science, a rotational shear vane is commonly used in the field (Fig. 13). The shear vanes come in different sizes, with larger vanes deployed in weaker soils to improve accuracy. A measurement of shear strength is calculated from the torque that needs to be applied to rotate the vane. Measurements can be made at different depths by pushing the vane deeper into the soil.

A range of other approaches can measure shear strength in the field, including a combined sinkage and shear device called a bevameter. Another approach is to insert a metal box into the top of the soil to a prescribed depth, excavate the surrounding soil to that depth, and then to winch the box horizontally, with the applied force recorded. Weights can also be placed above the soil for Mohr-Coulomb analysis (Eq. 20). This approach has been deployed to measure the reinforcement of soil by plant roots.

Fig. 12 A rectangular sinkage plate.

Fig. 13 A rotational shear vane. The torque required to rotate the vane in soil until it fails and the size of the shear vanes are used to calculate shear stress.

Soil mechanics and land management

Soils can be managed so that mechanical damage is avoided or mitigated, and to retain or improve mechanical properties to provide greater stability. Direct damage to soil arises from traffic deforming the soil by compaction, which is covered in detail in another article in the encyclopedia. Lighter machinery can decrease the stress and therefore strain experienced by the soil. Moreover, elastoplastic (and even viscous) deformation can be avoided by timing traffic on soils when they are drier and behave more as an elastic material that can withstand and recover from stress.

Tillage, predominantly by shear and fracture failure, breaks up compacted soils, resulting in drops in the precompression stress (Fig. 6), penetration resistance (Fig. 11) and shear strength (Fig. 13). Roots can therefore penetrate the soil more easily, but the weaker soil may also be more vulnerable to mechanical stresses from rainfall that leads to erosion. Poorer soil stability following tillage can increase viscous flow, so the tilth produced by tillage may slump over time.

Biology has a large impact on soil mechanics. Large-scale slope stability, for instance, can be improved by planting vegetation to provide reinforcement of soil by roots. Likewise, removing plant roots can make soils more vulnerable to damage by traffic, as occurs with overgrazing by livestock. At smaller-scale, biology binds soil particles, resulting in aggregation and the creation of a complex pore network. Microorganisms and plant roots excrete *exo*-polymeric substances that are surface active and act like glues. Fine plant roots and fungal hyphae provide stabilization at a slightly larger scale. These mechanical processes drive soil aggregation,

but they are often overlooked and rarely quantified in predominantly observational research on soil structure formation (Hallett et al., 2013).

Outlook

The mechanical behavior of soil is a fundamental physical property that is highly relevant to numerous soil functions, especially related to soil structure and stability. Two of the biggest threats facing soils, compaction and erosion, are driven by the resistance of soil to mechanical damage from traffic or rainfall, respectively. Mechanical deformation occurs when an imposed stress exceeds the strength of the soil. Beyond a critical stress, failure of the soil may occur either with negative consequences such as landslides or with positive impacts such as crack elongation to form soil structure. As surface soils are structurally complex and unsaturated, theories adopted from geotechnical engineering are insufficient to describe their mechanical behavior. However, advances in recent years and improved computer power have improved understanding substantially, including the use of X-Ray CT imaging to visualize localized deformation processes. The importance of soil pore structure is now widely appreciated, but moving forwards, the role of soil mechanics in the genesis and deformation of soil pores needs greater consideration.

Readers wishing to learn more about soil mechanics are guided to the following books:

Wesley (2010) introduces the fundamental of soil mechanics using at a range of geotechnical engineering applications as examples.

Lu and Mitchell (2019) provides up-to-date overview of soil mechanics with special focus on geotechnical engineering.

Lu and Likos (2004) as well as Fredlund et al. (2012) introduce unsaturated soil mechanics from a soil science as well as a geomechanics perspective.

De Boer (2000) provides an introduction to soil mechanics based on porous media theory as well as an excellent review of the history of soil mechanics.

Abstract

Soil compaction is a decrease in pore space driven by mechanical stresses. It is prevalent in agriculture, forestry and construction due to too high wheel loads by machinery, leading to adverse impacts to drainage, aeration and soil strength that affects plants and exchanges between soils and the wider environment. Compaction arises when a mechanical stress exerted on the soil exceeds its internal strength. The applied stress attenuates with depth, but mitigating subsoil compaction is more difficult than compaction of the upper soil layers.

Key points

- Soil compaction by the weight of machinery or animals causes a loss of porosity and pore connectivity.
- When the compaction stress exceeds a critical value, plastic deformation results in no recovery of soil pores when the stress is removed.
- Lighter machinery, low ground pressure tires and driving on fixed tramlines are approaches to decrease soil compaction risk.
- Compaction damage can be reversed in the topsoil by tillage or natural processes, but recovery may take a long time and subsoil damage by compaction is irreversible.

Introduction

Soil compaction occurs when an exerted mechanical stress on soil exceeds its internal strength. Pore space is lost with compaction, which can adversely impact soil functions including habitat for soil biota and roots, flood regulation, and climate regulation. The resulting environmental consequences extend beyond on-site impacts to the wider landscape. Compacted soils tend to have poorer capacity to produce plants, whether for agriculture, forestry or amenity purposes.

Compaction is a process of densification and it is typically associated with distortion, in which total and air-filled porosity and permeability are reduced, and soil strength is generally increased. Compaction typically also changes soil pore connectivity and continuity, hence modifying soil structure and associated properties. The term 'compaction' is used to identify a process and should be distinguished from the term 'compactness,' which indicates the state of packing of the solid soil constituents at a given time and position.

There are many causes of soil compaction, but here we focus on stresses exerted by machinery or grazed livestock. With machinery, the compaction process can be initiated by wheels, tracks or rollers of traffic such as tractors, depth-control wheels on cultivators and packer rollers. Soil densification can also be caused by heavy overburdens of ice and snow, by natural and management-induced hard-setting, and by illuviation of clay from the A-horizon into the B-horizon. These processes may take place slowly over long periods of time and result in the B-horizon having much greater bulk density and strength than the A-horizon. Densification also occurs during structural collapse near the soil surface due to the impact of rain, resulting in the formation of surface crusts.

In arable land with annual plowing, both topsoil and subsoil compaction should be considered. We define the subsoil as the soil beneath the regularly loosened layer (that is about 20–35 cm thick). This definition of the subsoil includes the pan layer as the upper part of the subsoil. This pan layer is, in many cases, less permeable for roots, water, and oxygen than the soil beneath it, and is the bottleneck for subsoil functioning. In contrast to the topsoil, the subsoil is not loosened annually but compaction is cumulative and, in the long run, a more or less field-wide compacted layer is created. The natural recovery potential of the subsoil is low, and therefore, subsoil compaction is nearly persistent. Evidence from field studies demonstrate that impairment of soil physical properties caused by subsoil compaction remains for decades (Berisso et al., 2012; Keller et al., 2017). An important cause of subsoil compaction is moldboard plowing in which the furrow-side tractor wheels apply appreciable loads directly to the upper surface of the subsoil, causing a plow pan.

Problems of compaction are widely distributed throughout the world, but tend to be most prevalent and increasing where heavy machinery is used in agriculture or forestry, in both temperate and tropical areas (Keller et al., 2019). Soils that are naturally fragile in structure, such as soils of humid tropical forests and light-textured soils in areas of low but erosive rainfall, are particularly prone to problems arising from compaction and subsequent high risks of erosion due to a reduction of permeability. Compaction is one of the major threats to soil resources. Estimates of land area affected by soil compaction are still uncertain, but studies in the 1990's state that around 35% of all arable land is affected by compaction in regions with heavy mechanization (Oldeman et al., 1991). Moreover, soil compaction was reported to be equal to or exceed 33 Mha of agricultural land in Europe and 18 Mha in Africa. A project on mapping of Soil and Terrain Vulnerability in Central and Eastern Europe (SOVEUR) by the United Nations Food and Agriculture Organization (FAO) and International Soil and Reference Information Centre (ISRIC) showed that compaction is the most widespread form of soil physical degradation on agricultural land in Central and Eastern Europe (Nachtergaele et al., 2002; Batjes et al., 2014). It has been estimated that about 25 Mha agricultural land was lightly and about 36 Mha moderately compacted in the year 2000. Soil compaction results in significant costs, both directly for the farmer in terms of, among others, yield loss and higher fuel use, and indirectly for society due to erosion, higher greenhouse gas emissions, flooding and landslides. Reliable estimates of the ecological and economic costs of soil compaction remain, however, difficult to assess.

Factors and processes affecting the distribution and intensity of compaction

When the stress applied to the surface soil exceeds a critical value, the soil compresses and does not recover when the stress is removed. Generally, the expression of soil strength used for soil compaction risk evaluation is the precompression stress, also called preconsolidation stress. It is defined from the sharp bend observed on the strain - log(stress) curve obtained from the uniaxial, confined compression of soil cores (Fig. 1). At stresses smaller than the precompression stress, the rate and amount of deformation is small and if the applied load is removed, the soil returns to its original structure as an elastic material. Once the precompression is exceeded, deformation is greater with increasing applied stress and the soil does not bounce back when the stress is removed. This expression of soil strength is somewhat idealized and originates in civil engineering soil mechanics (Casagrande, 1936) where it was introduced to characterize the reversible (elastic) and persistent (plastic) strain of homogenized clay during slow consolidation. Because the precompression stress represents the strength of a soil, we call it the precompression strength. In agricultural soil science with structured soils, exceeding of the precompression strength will result in plastic deformation with destruction of the structure including irreversible changes of properties and functions (Horn, 2003).

A Virgin Compression Curve based on a one-dimensional compression test on soil is shown in Fig. 1. It is usually measured using very slow tests that allow for soil drainage, following the approach developed for geotechnical engineering. The downward compression stress is referred to as the normal stress. Soils may also experience shear and tensile stresses that have elastic and plastic components and can occur concurrently with compression to create complex stress fields.

Fig. 1 Example of strain - $\log(\text{stress})$ experimental points obtained from a uniaxial, confined compression test. The precompression stress is defined as the stress at the sharp bend of the curve. Soil submitted to stress larger than the precompression stress or precompression strength will be compacted irreversibly following the virgin compression line.

Compaction under running gear

Compaction under wheels and tracks is a dynamic process in which a soil volume beneath the running gear is subject to normal and shear stresses that cause normal and shear strains. Fig. 2 illustrates how soil volume elements are affected by the passage of a wheel. During a wheel pass, a volume element at a certain depth endures not only volume change (i.e., compaction) but also distortion (i.e., shear deformation), as depicted by the volume elements 9–26. The soil displacement and deformation is also dynamic across the wheel track, due to differences in stress-state in the ground contact area, as can be seen in Fig. 3. The impact of a wheeling event on physical properties of the soil depends on the ability of the soil to resist the exerted stresses, i.e., on the strength of the soil. If the exerted soil stresses exceed the precompression strength or shear strength of the soil, then compaction or shear deformation will be accompanied by permanent structural deformations. This is what the wheel-load carrying capacity concept (Van den Akker, 2004; Van den Akker and Schjønning, 2004) is based on. Degradation of soil structure will be less severe if only the precompression strength is exceeded. In this case, the soil will mainly compress with limited distortion, and the soil pores will still retain a certain continuity.

Effect of loading characteristics on contact and soil stress

Loading characteristics such as choice of tire or track, wheel load and inflation pressure are used to estimate the magnitude of stresses exerted on soil. Examples of loading situations for various vehicles and animals are shown in Table 1.

For practical purposes, the mean ground contact pressure P (kPa) is a useful parameter, defined as the wheel load divided by the ground contact area. The distribution of the load in the contact area is, however, hardly uniform under running gear on a deformable surface. Instead, the distribution is generally well described by a parabola, with a maximum stress at the centerline and zero stress at the edge of the ground contact area. The maximum stress in the ground contact area, that are typically much greater than P , determines the peak stress in the soil.

Peak stresses under caterpillar tracks are two to four times the mean ground contact pressure, and depend strongly on the firmness of the soil and design of the track system. Peak stresses under lugs can be two to five times higher than the mean ground contact pressure. The resulting soil stresses decrease, however, rapidly with depth, because the ground contact area of the lugs is small. If soil stresses at a depth of 0.2–0.3 m are considered, the peak stresses under the lugs can be neglected. Still, a parabolic stress distribution, with a maximum stress of one-and-a-half to two times the mean ground contact pressure generally provides a good estimate of the vertical stress distribution.

The stresses distributed in the ground contact area propagate into the soil profile. The larger the wheel load, the deeper into the soil the stresses propagate. Moreover, stresses propagate deeper when the soil is weaker. Track or tire dimensions and tire inflation pressure are the main drivers of stress in the upper depths of the soil (Arvidsson and Keller, 2004; Van den Akker, 2004), yielding smaller stresses for larger dimensions and lower pressures. Therefore, Low Ground Pressure tires can considerably reduce the risk of

Table 1 Examples of loads and ground contact pressures applied by agricultural and forest vehicles, and by animals.

Source	Total load (kN)	Load per (rear) wheel/track/hoof (kN)	Ground contact area (m ²)	Mean ground contact pressure (kPa)	Peak stress in ground contact area (kPa)
Tires					
270-kW tractor	100	40	0.65	65	170
65-kW tractor	40–50	10–15	0.2–0.3	40–75	90–200
Combine harvester (loaded)	250	85	0.75	110	220
Slurry tanker (loaded)	210	35–52	0.5–0.67	75–110	140–270
Forwarder	70–110	17–30	0.4–0.8	85–220	100–440
Tracks					
Tractor with tracks	140	70	2.6	30	80
Forwarder with tracks	100–140	35–70	2.0–2.4	55–75	100–150
Animal					
Horse	8	2–8		75–300	
Cow	4–6	1–6		120–480	

Note that ground contact area depends also on tire inflation pressure, tire flexibility and rut depth.

Fig. 4 Increase of bulk density to considerable depth when a bulldozer was used for forest clearing in Surinam (—no vehicle traffic; — bulldozer traffic). Reproduced with permission from Van der Weert R (1974) *Tropical Agriculture (Trinidad)* 51(2): 325–331.

soil compaction compared to standard tires (Ten Damme et al., 2020). The benefit gets smaller the deeper into the soil profile the stress propagates. Deeper in the soil profile, stress relates more closely to wheel load instead, which can be explained by the Söhne (1953) summation procedure: a pseudo-analytical continuum concept based on the Boussinesq (1885) solution for stress propagation in an isotropic half space medium. Compaction by heavy machinery extends then well into the subsoil (Fig. 4), despite the fact that heavier machinery generally has larger tires compared to lighter machinery.

However, many machinery-soil interactions that may influence the stress-state and distortion rate in soil remain poorly understood. Among these interactions are the effects of traction, repeated wheeling and loading time. More traction increases the risk of pore distortion due to changes in the stress state in soil (higher horizontal stress relative to vertical stress) and has been pointed out as a factor that explains greater subsoil deformation for smaller wheel loads (Pulido-Moncada et al., 2019; Ten Damme et al., 2021). With increasing loading time and number of wheeling events, soil deformation may gradually increase without substantial changes of the stress state.

Soil compactibility

Soils can vary in their ability to resist deformation, from being sufficiently strong to resist applied loads (low compactibility) to being so weak that they are compacted by even small loads (high compactibility). Well-structured soils combine good physical soil

properties with adequate strength compared to badly structured soil. Sandy soils with a single-grain structure and compacted massive soils can be very strong, but rootability and soil physical properties are then often poor. Roots have a reinforcing action and increase the elasticity and resistance of a soil to compaction.

Soil moisture content and soil water suction have dominant influences on soil compactibility. In soils where capillarity by water is the main cohesive force, strength increases with drying until it reaches a maximum, and then again decreases upon further dehydration because the cross-sectional area of the water menisci decreases so the impact of capillary suction is less. This cohesive force based on soil water suction is called apparent cohesion (Koolen and Kuipers, 1983). Drying also increases the true cohesion because cementing agents concentrate in the connecting points between the soil grains. Soil water suction increases the cohesion significantly and in this way the strength and resistance to compaction of a soil can vary considerably. In dry structured (aggregated) soils, soil water concentrates in the aggregates, and cohesion and soil strength in the aggregate increases considerably. Drying structured soils shrink and turn into an assembly of individual aggregates that fit together rather neatly. This assembly of aggregates has a very high interaggregate angle of internal friction and moderates interaggregate cohesion. This soil is strong and has a small compactibility. However, if such a soil is overloaded and compacted, the aggregates will be crushed and the interaggregate space will be lost, resulting in a dense compact soil.

Dry soils can easily resist loads. However, extremely dry sandy soils lose their apparent cohesion and can be deformed and compacted under small stresses. With increasing moisture content, soil compactibility increases until a condition known as the optimum moisture content for compaction is reached (Fig. 5A). At still wetter moisture contents, the soil becomes increasingly incompressible as the moisture fills ever more of the total porosity and further loss of air-filled porosity becomes impossible. Saturated soil is incompressible because water is incompressible. However, in reality, soils are hardly ever fully saturated. Although compaction may be minimal in field-saturated soils, the plastic flow of a wet soil results in a degradation of soil structure and macropores with accompanying diminishment of soil physical quality (Dawidowski and Lerink, 1990). Hence, dry and strong soils may be largely elastic, whereas at high moisture content and low strength, the soil's reaction to loading may be plastic flow.

Fig. 5 Changes in (A) total porosity and (B) saturated hydraulic conductivity of a sandy clay loam subjected to field traffic during seedbed preparation with low ground pressure (marked as '.....', tire inflation pressure 40 kPa) or high ground pressure (marked as '- - -', tire inflation pressure 80 kPa) with the same wheel loads or subjected to uniaxial stresses of 0.1, 0.2, 0.4, 0.6, and 0.8 MPa at various water contents. Solid lines refer to compression of aggregated mixtures (after Dawidowski and Lerink, 1990). Increases in organic matter content tend to increase soil compactibility but also increase soil elasticity, the latter resulting in greater compaction resilience of pore structure. Peat soils dominated by organic matter, for instance, are quite resilient to compaction, despite initial large deformations. The value of the optimum moisture content for compaction increases as the organic matter content increases.

Effects on soil physical and mechanical properties

Bulk density, porosity, and packing state

Dry bulk density (the mass of soil solids per unit volume) is a direct and easy-to-measure indicator of changes in compactness. As it is calculated from the mass of material in a given volume, bulk density is affected by both porosity and particle density. At the same bulk density, a soil with a greater soil organic matter content will have a smaller porosity than a soil with less soil organic matter content. This impact can be removed by expressing changes in the packing state by total porosity or void ratio, described in the Stress-Strain and Soil Strength article. Total porosity is much easier to visualize than bulk density, as it is the total volume of pores in a given volume of soil. Void ratio is the volume of pores in relation to the volume of solids only.

Between soils of different textures, bulk density and porosity can change markedly, so it is difficult to interpret compaction occurrence from these measurements alone. Relative terms for packing state (e.g., relative density, degree of compactness) provide a ratio between a 'compacted' and 'uncompacted' state of the same soil. These enable the same threshold values to indicate over-compaction for soils with different texture (Håkansson et al., 1988).

Compaction primarily causes major reductions in macroporosity ($>50\ \mu\text{m}$), reduction of total porosity, and often an increase in microporosity. Major changes to hydraulic conductivity and gas diffusivity result, due to compaction impacts to pore architecture, i.e., pore size distribution, pore connectivity and continuity.

Hydraulic properties

Saturated hydraulic conductivity is very sensitive to the compaction process by wheels, especially if the deformation includes shearing and kneading of the soil. Fig. 5 shows that wet soils are easier to compact than dry soils, and that the effect on the saturated hydraulic conductivity is more than proportional to the compaction. In Fig. 5A the vertical stress in the topsoil beneath the Low Ground Pressure tire can be estimated at about 130 kPa (0.13 MPa) and beneath the High Ground Pressure tire on about 220 kPa (0.22 MPa). However, the compaction levels expressed in total pore space are comparable to uniaxial stresses in the range of 0.5–0.3 MPa. This can be explained by the dynamic stress field including shear stresses under wheels and resulting distortion of structure by shear failure resulting in the greater degradation of soil qualities than observed in uniaxial tests.

The decrease of macroporosity and increase of microporosity in the process of compaction results in larger water contents for a wide range of matric potentials in compacted versus uncompacted soil. The consequence is that compacted soils are generally characterized by a higher unsaturated hydraulic conductivity compared to their uncompacted state. However, near saturation, meso- and macropores are also water filled and contribute to the hydraulic conductivity. Thus, the saturated and near-saturated hydraulic conductivity of an uncompacted soil is greater than that of a compacted soil.

Aeration characteristics

A consequence of compaction is a reduction in the air-filled pore space. The air-filled pore space is an indication of the aeration status of the soil for plant growth and microbial activity. At air-filled porosity values less than 10%, oxygen deficiency is likely, especially in warm weather, whereas values less than 5% probably indicate incipient anaerobiosis. Analogous to saturated hydraulic conductivity, aeration status depends strongly on soil structure and continuous macropores. In a poorly structured compact soil, threshold values for air-filled porosity of 20% (oxygen deficiency) and 10% (anaerobiosis) are often used to indicate structural condition. In a well-structured soil, oxygen deficiency may start below 5% air-filled porosity and anaerobiosis below 2.5% air-filled porosity. Other indices of aeration status, such as oxygen diffusion rate, oxygen content of soil air, and air permeability, provide more precise indicators of the aeration level. Compaction that involves shearing disrupts pore continuity, which can decrease aeration with minimal changes to total porosity. Therefore, the values listed above only provide a rough estimate.

Soil strength characteristics

Soil strength resists the stresses causing compaction, and tends to increase with compaction. However, at the same bulk-density and moisture content, a well-structured soil resists stresses better than a poorly structured soil under moist conditions, Horn (2003). A wet soil is generally weaker than a dry soil. In periods with wet-weather conditions, compacted soils tend to become wetter than uncompacted soils due to limited infiltration capacity, smaller saturated hydraulic conductivity, and large microporosity. Consequently, the strength and trafficability of compacted soils become lower than that of well-structured soils that drain more readily. After a wet period, a compacted soil will stay wet longer with limited workability. In a dry period, the strength of a compacted soil will increase considerably and result in high trafficability. Soil tillage then requires more powerful equipment and a higher energy input to loosen the soil and break up clods of soil into fragments that form a good seedbed.

Compaction increases the penetration resistance for roots, resulting in limited rooting depth and reduced crop growth. At penetration resistances (measured with a cone with a diameter of 12.7 mm and top angle of 30 degrees) of 1.5 MPa and 3.0 MPa, root growth rates of many crops are reduced to approximately 50% and 0%, respectively. However, in well-structured soils, roots can make use of continuous macropores to penetrate deeply into the soil. In drying soils, strength and penetration resistance increase.

Compaction in crop production

Although compacted soils usually have unsatisfactory physical conditions for plant growth, the extent of loss of productivity depends on soil type, plant species, and weather conditions.

Effects on germination and establishment

Compact soils result in cloddy seedbeds after primary and secondary tillage, poor soil-seed contact, and reduced germination. Soils may develop a compact surface layer due to crusting after heavy rainfall, which has sufficient strength to restrict or even to inhibit seedling emergence, in particular for dicotyledonous species.

Effects on root growth and root distribution

Macropores ($>50\ \mu\text{m}$ diameter), through which roots can generally proliferate readily, are much reduced in compacted soil. As a result, root growth is restricted in development and depth or even inhibited. In Fig. 6, the limitations to root growth are

Fig. 6 A conceptual relationship between soil porosity and soil water potential in which soil aeration and mechanical resistance (PR, penetration resistance) meet specified root requirements. Root growth is insufficient in the red and blue shaded areas and impossible beyond a soil water potential of $-1500\ \text{kPa}$ (pF 4.2). Added to the figure are the same relationships if the structure is deteriorated resulting in a strong reduction of macropores (bad structured soil) (after Boone, 1988). Reproduced with permission from Lindstrom MJ and Voorhees MB (1994) *Soil Compaction in Crop Production*. Amsterdam: Elsevier.

conceptualized as relations between soil porosity and soil water potential at which soil aeration and mechanical resistance meet specified root requirements. In a soil with a certain pore volume, the soil water suction determines whether root growth is limited by too high mechanical resistance, by aeration problems, or is not limited. In Fig. 6, the two thin lines show the situation in the case of a poorly structured soil. A poorly structured soil with few continuous macropores needs more air-filled pores for aeration than a well-structured soil. Likewise, much smaller mechanical resistances are allowed in a poorly structured soil than in a well-structured soil because roots can follow the macropores in the well-structured soil.

Effects on plant growth, crop yield and soil biota

The level of compactness (often expressed in dry bulk density) influences the growth, yield, and quality of crops, although the impact depends on crop species, soil type, and weather conditions (Fig. 7). The optimum level of compactness for crop growth tends to be higher for sandy soils, in dry seasons, and for monocotyledonous species. At a compactness level less than optimum, crops suffer from reduced soil-root contact, reducing germination and nutrient transfer, while at a compactness level higher than optimum, root growth and aeration are restricted and denitrification can lead to N losses.

Soil biota and biological processes are influenced by soil compactness. This is partly because of the influence of pore size distribution and connectivity on the volume and connectivity of habitats for soil fauna, bacteria and fungi, and partly because compacted soils modify soil moisture and aeration conditions and may suffer from anaerobiosis, which in turn affects microbial metabolism markedly. The burrowing abilities of soil fauna, particularly earthworms, are reduced in compacted soils.

Interactive crop responses to compaction and fertilizer application

When farmers note that the growth of crops is adversely affected by compacted soils, a common action is to apply additional N fertilizer. However, the growth responses obtained may be less significant than those at lower levels of compactness (Fig. 8), and the additional nitrogen applications may be inefficient economically and detrimental to the environment. This is extremely important for soil sustainability. For instance, in Fig. 8, a compacted soil at 1.54 g cm^{-3} bulk density requires $3\times$ the applied nitrogen to obtain the same dry matter yield as an uncompacted soil at 1.37 g cm^{-3} bulk density. In compacted soils, roots are restricted from deep rooting, so if leaching occurs nitrogen is lost. Moreover, the poorer aeration status of compacted soils results in greater gaseous emissions of applied N, causing N-losses and producing N_2O .

Crop responses to subsoil compaction

Amelioration of subsoil compaction is much more expensive and less effective than loosening compacted topsoils. Avoidance of compaction in the subsoil is therefore a much greater need than in the topsoil. Seventeen years after a single full-field compaction action, crop and nitrogen yield losses can still be significant on compacted sites (Fig. 9). In this long-term experiment (Alakukku, 2000), only moderate axle loads were allowed on the fields after the initial compaction, to give the topsoil and subsoil the possibility to recover by natural processes. It should be noted that in practice, subsoils will endure heavy wheel loads from time to time, so most subsoils in agricultural fields are more or less partly compacted every year. This means that in practice, the recovery time of subsoils is limited, and the subsoil quality is never regained as much as in the long-term experiments. Note that the compaction effect was more pronounced in all years for harvested nitrogen than for grain dry matter. The strong decline of the effect in the first few years was mainly due to the recovery of the topsoil. The effect of compaction on grain and nitrogen yield was

influenced by rainfall during the subsequent growing seasons. In dry seasons, a moderately compacted subsoil sometimes may result in yield advantages due to reduced loss of soil water percolating below and out of the reach of the root zone. In wet seasons, however, the reduced permeability of the subsoil can lead to anaerobic conditions within the topsoil, resulting in direct damage to the crop and loss of nitrogen by denitrification. In dry seasons, compaction may prevent roots from growing into the subsoil due to high soil mechanical resistance, which limits the plants access to resources (particularly water and nitrogen) in the subsoil.

Modeling of crop responses to soil compaction

Crop growth does not reach its full potential when the uptake of water, oxygen, or nutrients is less than the demand of the crop. Potential crop growth is determined considering the prevailing weather conditions. Reduced crop growth may be caused by a reduction of the length of the growing period, low temperature, limited supply from the soil of water, oxygen, and nutrients to the root system, and a limited activity of the root system. Soil water plays a central role in these limiting factors, and effects of soil

compaction on crop growth and biological functioning in relation to water are crucial. In Fig. 10, a scheme is presented of the interrelationships among soil tillage, field traffic, soil structure and soil physical, chemical, and biological properties. A part of this scheme is considered in more detail in Fig. 11. To simulate crop responses to soil compaction, all aspects presented in Figs. 10 and 11 should be included in a model. However, most crop models do not include all aspects, such as limitations of root growth due to increased soil mechanical resistance or lack of aeration, the role of macropores, reduced accessibility and availability of nutrients (e.g., loss of nitrogen by denitrification), and effects of reduced biological activity, and tend to underestimate the impact of compaction on crop growth.

Effects on environmental components

Soil compaction influences a number of environmental parameters, even at considerable distance from the original location at which the compaction occurred (Fig. 12). Compaction may change the fluxes of greenhouse gases from the soil to the atmosphere through mechanisms associated with effects on soil permeability, aeration, and crop development. Compaction increases CO₂ emissions because cultivation of compacted soils requires appreciably more energy than cultivation of uncompacted soils. Approximately 90% of the global N₂O emissions to the atmosphere come from soils. Compacted soils tend to be wetter than noncompacted soils, so denitrification is enhanced. The flux of N₂O increases rapidly as air-filled porosity declines (Fig. 13). Compaction from vehicle traffic prior to the establishment of cereal crops can cause marked increases in the N₂O fluxes during the early growth period in spring (Table 2).

Table 2 Influence of vehicle traffic (zero, light, heavy) prior to the establishment of wheat and spring barley on N_2O flux during the early spring growth period.

Crop	Period (dates and days)	Cumulative N_2O flux ($g\ N_2O-N\ ha^{-1}$)		
		Zero	Light	Heavy
Spring barley	16 May–14 July = 60 days	320	310	401
Winter wheat	8 March–8 May = 62 days	245	210	578

Adapted from data in Ball BC, Parker JP, and Scott A (1999) *Soil and Tillage Research*. Amsterdam: Elsevier.

Due to reduced permeability, compacted soils usually show greater runoff and hence greater risk of flooding and erosion than noncompacted soils. Surface rills and even gullies are sometimes directly associated with wheel tracks, particularly over seedbeds following periods of highly erosive rainfall. Surface waters may thus carry additional burdens of clay and silt, fertilizer, and pesticides when runoff occurs from areas of compacted soil.

Measurements of soil mechanical stresses

The stress state at a given point in the soil can be determined using strain gauge pressure transducers, more commonly called 'load cells' (Lamandé et al., 2015). Alternatively, one can use vibrating wire strain gages or strain gauge transducers, or fluid inclusion type probes. The strain-gauge pressure transducers can measure normal stresses and relate the stresses to a direction depending on the orientation of the transducer in the soil. The measurements may be made in a single or multiple directions simultaneously by a single load cell, depending on the number of faces of the transducer (Wiermann et al., 1999). Fluid inclusion probes may also be able to read stresses in specific directions, but usually they are used for measurements of mean normal stress.

The magnitude of stresses at a given point in the soil during wheeling is dynamic both in and across the driving direction. Several, similar sensors for measurements of a given stress across the full width of the wheel track provide the distribution of stresses during wheeling. However, to gain a complete picture of the stress-state under running gear, stresses need to be measured in multiple directions (the principal stresses, and mean normal and octahedral stresses). Stresses can be measured at different depths, which provides information on the propagation of stresses into the soil.

Strategies for the prevention of compaction

Options to manage soil compaction include minimizing compaction risks by adjusting induced stresses to soil strength, and restricting compaction to small areas such as tramlines as practiced in controlled traffic farming. The stresses induced by vehicles can be minimized by reductions in overall mass and reductions in wheel loads, and by increases in ground contact area and reduction of ground contact pressure. Low ground contact pressure will mainly reduce soil stresses in the topsoil and upper subsoil, as soil stresses in the deeper subsoil are primarily governed by the wheel load. Tires of greater width and diameter will increase ground contact area if combined with a reduction in inflation pressure (Ten Damme et al., 2020), and thereby reduce the ground contact pressure for a given wheel load. Limits in tire inflation pressure will also result in limiting the wheel load of that specific tire. The development of flexion technologies has played an important role here; inflation pressures for a 30 kN wheel load reduced from 140 kPa for a 16.9 R28 tire to 0.6 kPa for a 710/70 R 42 tire. Multiple axle systems (in particular tandem axles for trailers and tankers with low-pressure tires) reduce wheel loads and provide extra contact area, however, increase the number of times soil is wheeled if the axles are not positioned in an offset configuration. Dual wheels and tracks also allow for a larger ground contact area. However, if not implemented correctly, one risks compacting a larger soil volume. For tracks in particular, it is important to balance the machinery well to avoid high stresses under the front or rear of a vehicle, and to reduce peak stresses concentrated under the wheels and supporting rollers. In general, it is of primary importance to reduce wheel loads to reduce stresses in the deeper soil layers.

Tool-carriers (gantries, controlled traffic farming), up to 12 m width, have been found capable of providing traffic-free zones in which tillage requirement is reduced (because of the lack of compaction) and crop yield and crop quality may be improved. Vehicle traffic can also be reduced by combining different operations into a single-pass operation. However, an increase of wheel loads should be prevented.

Most importantly, the strength of the soil at the moment of field traffic should be considered. Trafficking and working soil when it is too wet should be avoided to preserve soil structural and mechanical stability. Tillage should be reduced as much as possible to optimize biological and physical processes that improve soil structure, in particular macroporosity.

Improving drainage will result in drier hence stronger soils. Increases in soil organic matter, either as a surface mulch or incorporated, will improve soil structure and increase soil elasticity and resilience and thereby reduce the risk on irreversible compaction.

Strategies and recommendations for prevention of soil compaction in agriculture often rely on simulation models. Such soil compaction models calculate stress propagation and soil failure in the soil profile for certain wheel or track loading characteristics and soil conditions (e.g., soil water content). Usually, these models use a stress propagation in the soil profile based on the theory of elasticity. A comparison between measured and simulated soil stresses highlighted the importance of accurate stress readings and realistic upper model boundary conditions, and suggested that the actual stress transmission could be predicted accurately according to the theory of elasticity for the conditions investigated (Keller et al., 2014). One approach in risk assessment using soil compaction models involves a quantitative comparison of stresses transmitted to the soil profile with soil strength, enabling evaluation of the risk of soil compaction for specific machinery and soil conditions. Often precompression stress is used as soil strength. Although there are some questions about the use of precompression strength (Keller et al., 2012) such tools can help farmers and advisors in planning and making decisions about specific traffic situations in the field. This approach can be used in decision support systems (e.g., www.terrano.dk), for example, in choosing the right equipment or tires. Comparisons of loading and soil conditions can also be used for mapping, for example, the wheel load carrying capacity (Schjønning et al., 2015) or for calculation of the number of trafficable days.

Simple rules of thumb to reduce soil compaction risk have been proposed. For example, at water contents around field capacity, traffic on agricultural soil should not exert vertical stresses in excess of 50 kPa at depths larger than 50 cm (Schjønning et al., 2012). Also, maximum values of mean ground contact pressures are recommended for different soil conditions to minimize topsoil and subsoil compaction, ranging from 80 kPa for wet soils in spring to 200 kPa for dry soils in summer (Tijink, 1998).

Compaction in forestry

Forestry operations often exert a large number of wheel passes with large wheel loads on very moist soils. Due to the rough forest environment with roots, branches, rootstocks, and often stones, and the highly dynamic wheel loads, tires of forest vehicles must be wear-resistant and with high inflation pressures. This causes a high risk of deep subsoil compaction, which will be very persistent (Riggert et al., 2019). On the other hand, the frequency of forestry management and the area involved is less than arable agriculture. However, the almost nonexistent and often only partial recovery of compacted subsoils by natural processes causes the degradation of soil quality by subsoil compaction to accumulate over time. In addition to a decrease in forest production, this results also in a greater risk of erosion and shallower rooting and vulnerability to dry or wet periods. Subsoil compaction can be limited to a relatively small part of the area by using controlled traffic on permanent skid trails with fixed GPS coordinates. Reduction of subsoil compaction is at least partly possible by using tracks and the use of slash (brush mats) dumped on the trail.

Amelioration of compacted soils

Natural weathering due to freezing and thawing is usually restricted to the top few centimeters of the surface soil and rarely penetrates to the subsoil. Swelling and shrinking arising from changes in water content can cause changes in soil structure that may lead to an increase in total porosity. Deep rooting is important to dry out deeper soil layers to induce shrinkage and improve structure. Roots of certain species can penetrate compacted layers, thereby creating new pores, but this does usually not involve an increase in total porosity because roots push the soil aside when growing through soil. Over time, however, roots interacting with soil organisms can promote aggregation and restructuring of soil, thereby decreasing compaction. Earthworms can decompact a soil by ingesting soil and releasing cast on the soil surface. Such improvements of macroporosity greatly improve permeability and gas diffusivity of soil. In this way, gradual improvements can be made in the soil physical quality of compacted layers. However, highly compacted parts, in particular layers that cannot be penetrated by roots, will recover very slowly and possibly not recover at all.

Compacted topsoils can be loosened by tillage. However, in many cases loosened compacted soils are cloddy and require more intensive secondary cultivation to achieve suitable seedbed tilth. Loosening subsoils requires high-draft special equipment and high traction, but it destroys the existing continuous macropores, and weakens soil structure and strength. Subsoiling should be done when the subsoil is dry with a minimum of loosening and with the aim to form cracks. Many loosened subsoils recompact within a few years, resulting in worsened soil physical properties and rootability. The result is that subsoils that have been loosened once must be loosened regularly every 4–5 years. Therefore, before subsoiling the subsoil should be inspected to determine rootability, aeration status, and drainability, to avoid unnecessary subsoiling.

Outlook

Compaction is one of the greatest forms of degradation facing soils. The impacts on biomass productivity affects food and fiber production, while the impact on the soil environment exacerbates the impacts of climate change. Compacted soils store less water, restrict root growth, erode more readily and emit more greenhouse gases. More erratic weather due to climate change results in fewer workable days, when soils are dry enough during spring and autumn operations to resist the stresses of machinery.

Abstract

Bioturbation is the physical movement of soil by fauna or plant roots. The primary goal of bioturbation is for organisms to access resources in soil such as food, plant nutrients and water. Bioturbation includes soil translocation by burrowing and ingestion, soil deformation by organism expansion, and soil stabilization by compounds secreted by organisms and their tissue. These processes are extremely important to the formation of soil structure, with impacts to flow and transport properties. Damage to soils from intensive management, compaction or carbon depletion limits the capacity for bioturbation, but bioturbation also helps to restore degraded soils.

Key points

- Bioturbation is a key process in the formation and maintenance of soil structure.
- Bioturbation is caused by a range of organisms that live in soil, including plant roots, insects such as termites, and animals such as earthworms and burrowing mammals.
- *Penetrator* organisms push into soil whereas *excavator* organisms displace soil by carrying or shoveling it with limbs.
- Soil structure is altered by bioturbation through the translocation of soil by burrowing or ingestion, the mechanical deformation of soil by the forces from burrowing, and the secretion of mucilage and other compounds by soil-dwelling organisms.
- Changes to soil structure by bioturbation affect flow and transport properties of soil.
- Biopores are a product of bioturbation. These open channels formed by organisms are rapid transport pathways that also ease movement of subsequent organisms, especially root growth.
- Land mismanagement decreases the abundance and functional capacity of bioturbating organisms, with severe implications to soil.

Introduction

Bioturbation is defined as the alteration of soil structure induced by biological agents (i.e., plants or animals). More specifically, bioturbation comprises the biophysical processes that internally displace soil solids, induce the mixing of soil constituents, re-organize the physical pore spaces in soil, and redistribute soil organic compounds. There are many biophysical processes in bioturbation, which include direct impacts from crevice burrowing, soil ingestion and aggregate displacement, and indirect impacts from secretions by plant roots (rhizodeposition), earthworms (casts and mucus) or associated microorganisms. Bioturbation can enhance the transport of water and gasses, provide reusable channels for future root growth, and accelerate the rates of soil structure formation, thus mitigating adverse impacts of soil structure degradation and restore soil function.

Soil bioturbation in natural soils is central in forming and maintaining soil structure that provides essential ecosystem services for a variety of biomes. The resulting biopore networks provide preferential pathways for water flow and extend oxic conditions

deeper into soil profiles (Ruiz et al., 2021). Biopores act as hotspots for biological activity and create paths of least resistance for subsequent root growth (Colombi et al., 2017). For water, these structures improve deep recharge to groundwater (sometimes at the expense of enhanced risk of pollution) and improve overall soil water retention. Bioturbation has been shown to facilitate root growth, which can further enhance the amount of atmospheric carbon stored below ground in the form of root biomass and root exudates (Beer et al., 2010). Regions with rich plant-derived organic matter act to stimulate microbial activity (Kuzakov and Blagodatskaya, 2015) and provide nourishment for earthworms (Lavelle et al., 2007). Soil ingestion by earthworms can also augment microbial activity, stimulating the aggregation of soil particles, which also contribute to soil structure. The ensemble of effects attributed to soil bioturbation activity may enhance crop yields by up to 25% (Van Groenigen et al., 2014).

Bioturbation is central to carbon cycling through numerous processes. The most direct is through the growth and development of organisms for acquisition of nutrients and water; the secondary impact is the promotion of soil biological activity. Rhizodeposition and decaying roots temporarily sequester photosynthetically fixed atmospheric carbon in soils. The below-ground carbon investment can range from 20% to 85% of total plant biomass (Gabet et al., 2003). Fine roots are produced at annual rates of 0.3–1 kg per m² ground surface, depending on ecosystems (Ruiz et al., 2017), which are consistent with other estimates for primary productivity in the literature (Beer et al., 2007). These carbon investments become primary sources of soil organic matter (SOM), which provides energy for heterotrophic activities by many invertebrates.

Bioturbation can enhance soil structure formation rates by 1–2 orders of magnitude relative to abiotic processes. Invertebrates contribute considerably to the movement and mixing of soil, with earthworms reported to move 6.5–100 kg soil per m² surface annually, ants impacting up to ~3 kg soil per m² surface annually, and termites moving up to ~0.6–1 kg soil per m² surface annually (Gabet et al., 2003). In doing so, these organisms act to mix the organic constituents through upper soil horizons. Their activities may also help to reduce the runoff of nutrients such as nitrogen and phosphorus.

Organisms such as earthworms, miner bees, and rodents play an active role as ecosystem engineers, but physical constraints, nutrient availability and pH can prohibit their activity. A pedological example are the distinct horizons that form in temperate Podzols because low pH soils deter earthworm activity. Arid soils may be too dry or hard, and tropical soils may have very low pH (Ruiz et al., 2021), so ants, termites, and reptiles, adapted to these particular environmental niches, become the dominant bioturbators (De Bruyn and Conacher, 1990). This highlights the different strategies used by organisms to explore soil resources and create subterranean shelters across different biomes and climatic conditions. For example, termites are fascinating ecosystem engineers that build intricate galleries with specific architecture for regulating heat and moisture, superbly tuned to the functioning of symbiotic fungi they cultivate, and enabling their habitats to persist in warm tropical regions (Ocko et al., 2019).

When soils are intensively managed for agriculture, damage from compaction and tillage can impede burrowing. The current move towards less intensive tillage systems has an aim of restoring the capacity for biology, rather than mechanical cultivation, to form soil structure. This is especially important in regenerative agriculture, where soil bioturbation by plant roots and earthworms penetrating soil aid in restoring degraded soils.

Soil bioturbation processes and their impact on soil structure will be described in this chapter. Bioturbating organisms and their tunneling characteristics are listed, and split into those that generate tunnels through penetration processes (penetrators) and those that displace soil by carrying or shoveling it with limbs (excavators). The mechanics of bioturbation by growing plant roots and burrowing earthworms, both of which penetrate and expand soil cavities, will first be described. Then larger-scale bioturbation by mammals, and their resulting impact on soil functionality, will be shown. Granular transport by ants and termites, that dominate in drier and warmer regions, demonstrates climatic impacts. The chapter ends with a broader outlook of other bioturbation agents that affect soil physical properties.

Overview of bioturbation mechanical processes

Different organisms employ different strategies to accomplish resource exploration and niche formation via soil bioturbation. Organisms without limbs, such as earthworms and plant roots, generate biopores (largely) by axial penetration and radial expansion processes (Fig. 1a–d). Despite general similarity in the resulting cylindrical biopores produced by these two organisms, they differ in physical characteristics and form through slightly different mechanical processes. Plant roots impact mechanical stresses on the soil at the tissue level due to expansion of cells (Greacen and Oh, 1972), driven by the softening of cell walls by their polymers modifying in response to developmental cues and the environment (Fig. 1a). In contrast, organisms such as earthworms use their muscular system to displace (and sometimes ingest) soil under relatively wet conditions (Fig. 1c).

Limbed and toothed organisms can grab or shovel soil particles to form burrows and cavities (Fig. 1e–g) (Rosario Carotenuto et al., 2020). For clarity, we will designate these organisms as excavators. Examples of mammal excavators are rodents such as moles or badgers that use their claws and even teeth to break up and shovel soil to form burrows (Fig. 1e and f). Similarly, smaller organisms such as ants or termites make use of their mandibles to carry and displace soil particles (Fig. 1g).

Bioturbation processes are constrained by governing physical processes occurring across a range of scales, inhibiting penetrators vs excavators differently. A summary on their relative bioturbation activity can be found in Table 1. Bioturbation activity with respect to mass displaced per unit land area is compared to the amount of soil impacted by tillage activity, converted from soil volumes assuming a range of soil bulk densities from 1200 to 1800 kg m⁻³ (Or et al., 2021). While there are limited data on the absolute magnitude of annual mass impacted by soil bioturbation, estimates for the combined impact of earthworms and plant roots have been compiled and compared to that of tillage activity by humans (Table 1). Soil bioturbation impacts just over half the

Fig. 1 Primary bioturbation processes. Left panels (a–d) highlight bioturbation through penetration processes such as plant root growth (a) or peristaltic motion of earthworms (b). Their penetration-cavity expansion processes result in channels that form biopores in soil (c and d). The right panels (e–g) highlight excavation processes through rodents digging (e and f) or ants carrying out material (g). Figure was adapted from Ruiz S, Schymanski S and Or D (2017) Mechanics and energetics of soil penetration by earthworms and plant roots—Higher burrowing rates cost more. *Vadose Zone Journal* doi: 10.2136/vzj2017.01.0021; Rosario Carotenuto A, Guarracino F, Šumbera R and Fraldi M (2020) Burrowing below ground: Interaction between soil mechanics and evolution of subterranean mammals. *Journal of the Royal Society Interface* 17: 20190521.

Table 1 Soil bioturbation by different organisms based on displaced soil mass per unit area annually (note affected soil depth vary widely across biomes and plant species).

	Tillage	Plant roots	Earthworms	Rodents	Ants	Termites
Annually displaced soil mass per land area [kg m^{-2}]	150–230	0.3–1.5	6–100	0.4–5.5	3	0.6–1
Annually displaced soil mass [kg]	$2.2\text{--}3.2 \times 10^{15}$	$1.2\text{--}1.7 \times 10^{15}$	–	–	–	$10.8\text{--}18 \times 10^6$

Taken from Or D, Keller T and Schlesinger WH (2021) Natural and managed soil structure: On the fragile scaffolding for soil functioning. *Soil and Tillage Research* **208**: 104912.

soil volumes affected by tillage. Considering that tillage is one of the largest geo-engineering activities on earth, the impact of soil bioturbation is likely underestimated and plays a significant role in shaping terrestrial ecosystems.

While extending these estimates to other soil bioturbation organisms is difficult, estimates considering global maps of invasive termite species can provide rough estimates of their displaced soil masses (Buczkowski and Bertelsmeier, 2017). Termite activity affects roughly $18 \times 10^6 \text{ m}^2$ of terrestrial land, displacing soil masses estimated to range from 10.8 to $18 \times 10^6 \text{ kg}$ annually. There are many organisms that may contribute to soil bioturbation at similar orders of magnitude.

The subsequent sections will expand on the physical processes that underpin different types of soil bioturbation and elucidate how these processes are constrained by varying soil conditions, ultimately highlighting how soil physical conditions can explain particular niches for differing soil bioturbation activity.

Soil physical constraints to bioturbation

Organisms are constrained in bioturbation by soil moisture and strength. As soils dry, capillary forces from water begin to increase the cohesion between particles, with strength increasing further through chemical bonding when soils are very dry. Organic matter and soil aggregation can decrease the strength of soil experienced by an organism, with feedback occurring when these organisms regenerate the structure of soil. When soils are waterlogged, bioturbation will be limited by oxygen availability. For plants, root growth rates will be constrained as soils approach the wilting point at -1500 kPa water potential.

To overcome these physical constraints from soil, organisms have developed growth and burrowing mechanisms described below. The ecology of burrowing organism is strongly dependent on soil physical conditions, with penetrators dominating in temperate and excavators dominating in arid regions. Whereas a temperate region may provide a soft, moist soil that is easy to push through, an arid region has dry soil that is lighter to carry.

Bioturbation by penetrating plant roots

Plant roots must overcome soil mechanical resistance, water-logging and periods of drought during growth (Ruiz et al., 2019). To a great extent, plant roots can overcome these stresses with their remarkable capacity to exert large pressures (>1 MPa), to stimulate biological activity and to modify surrounding soil (the rhizosphere). Root growth deforms and displaces the soil matrix to form biopores that persist long after roots decompose. During their active growth, plant roots slough off cells and exude polymeric substances, presumably for reducing friction and improving hydraulic contact with the surrounding soil, which results in lining and reinforcement of biopores. Exuded polymeric substances also improve water retention, enhance soil aggregation and provide a conductive and living environment around the roots often seen as a rhizosheath (Basirat et al., 2019). Furthermore, root water uptake to meet atmospheric demand (transpiration flux) extends the depths and extent of soil drying. This, in turn, may enhance abiotic effects of wetting-drying cycles that can form cracks and assist soil aggregation.

The ability of roots to penetrate soil relies on multi-scale growth processes (Pritchard, 1994). At the molecular level, roots are largely constructed by parenchyma cells that maintain thin yet rigid primary walls with a remarkably high mechanical yield strength, estimated at around $0.5\text{--}2 \times 10^6$ Pa (Gibson, 2012). Extension of these cells occurs when their internal pressures exceed both the yield of the cell wall and the external mechanical impedance exerted by the surrounding soil. Cellular extension is complemented by an enzymatic loosening processes, causing periodic reorientation of cellulose fibrils in the cell wall (Pritchard, 1994). This enables tip wise extensional growth to reduce frictional effects near the root interface with the soil, and ultimately it allows roots to locally impart pressures upwards of $1\text{--}2 \times 10^6$ Pa; magnitudes great enough to fracture chalk rock (Misra et al., 1986). Under more mechanically stressed conditions, such as compaction, plant roots display a radial thickening in the zone of elongation behind the root cap (Hettiaratchi et al., 1990). The radial growth, primarily associated with the outer cortical cells, together with the enhanced production of root hairs by the epidermal cells, helps anchor the root behind the zone of cell extension. The internal arrangement of tissues limits the ability of roots to grow through smaller pores, as they lack mechanisms to become thinner. However, some studies have also suggested that radial thickening allows roots to exploit pre-existing fractures to propagate cracks. Alternatively, radial thickening may be the means of redistributing local stresses on the root. The multiscale growth process that enables plant roots to exert such high pressures also limits the actuation speeds of plants. Growth rates are constrained by poroelastic limitations, which are the fastest water driven actuation processes within a plant. As a result, root growth rates are in the order of $1\text{--}2 \times 10^{-7}$ m s⁻¹ (Dumais and Forterre, 2012) (Fig. 1a and b). A more rigorous mechanical description of this will be described later in the text.

The cumulative impact of a plants root system on soil is highly dynamic, as laterals growing out of primary roots are in a constant flux of growth and death. This results in an evolving network of tunnels. Furthermore, the accumulation of rhizodeposits in the rooting zone act to reinforce the tunneling structures. As such, these networks are more persistent than a pore produced through only mechanical means. The persistence of root biopores acts as a reliable avenue for subsequent preferential root growth, as they provide paths of least mechanical resistance. This is very important in particularly hard soils.

Beyond the biopores formed by root growth, bioturbation can result from root-soil entanglement, particularly for trees (Fig. 2). Root-soil entanglement acts to enhance bulk soil mechanical properties, reducing hillslope susceptibility to shallow landslides (Fig. 2b). However, the same entanglement by a root network can lead to a phenomena is known as tree throw (Fig. 2c) (Gabet et al., 2003). Strong forces associated with wind, snow overload, or even sufficient root decay can lead to the toppling of trees. As the tree falls, the soil mass entangled with the roots can be pulled out with the tree, resulting in a pit where the tree was originally rooted. Subsequent to the uprooting, the roots begin to decay, thus the soil is released, creating a mound that forms under the decaying tree. This process occurs over a period of 5–10 years (Gabet et al., 2003).

Bioturbation by earthworm burrowing

Earthworm bioturbation plays an important role in soil formation, stimulation of biological activity and in organic carbon transformations, thereby promoting soil health in temperate regions. As mentioned above, earthworm burrows improve physical conditions for soil ecological functioning (i.e., water flow, retention and aeration), and provide preferred pathways that can be reused by growing plant roots (Ruiz et al., 2021). Earthworms line their burrows with casts and mucus excretion, which incorporate organic constituents, making these hotspots for biological activity (Lavelle et al., 2007). Certain earthworm ecotypes (i.e., permanent deep burrowing anecic earthworms) are also known to pull leaf litter from the surface deep into their burrows (Palm et al., 2013). This activity enhances the pool of soil organic matter and augments the introduction of carbon to the profile, adding to contributions from root growth and decay. The mechanics of burrow formation follow two main processes; the primary is simply soil displacement by muscle actuation and hydroskeleton (Dorgan, 2010) action, and the other is by soil ingestion. Limited experimental evidence suggests that while earthworms ingest large quantities of soil, active burrowing is often done by mechanical means while in search of carbon rich regions in the soil (Ruiz et al., 2017).

The primary mechanism of earthworm burrowing is penetration-cavity expansion. This uses a system of circumferential and longitudinal muscles (i.e., their hydroskeleton) for mobility. Earthworms can alternate between contracting and stretching these muscle fibers in order to generate peristalsis (Fig. 3a–c) (Purves et al., 2003). This cyclic forward propulsion and subsequent expansion allows earthworms to penetrate and anchor into soil, enabling their ability to crevice burrow. From the action of their muscle fibers earthworms can produce actuation speeds on the order of $1\text{--}5 \times 10^{-4}$ m s⁻¹, which is three orders of magnitude faster

Fig. 2 Influence and scale of root-soil entanglement. The root-soil entanglement spans multiple scales from fine roots to rooting networks of an entire plant and even include multiple plants. (b) The presence of roots can act to mitigate landslides by acting to mechanically reinforce the soil. (c) For aging roots or dead vegetation, large winds and storms can act to uproot the tree; a processes known as tree throw. Tree throw can act to displace large volumes of soil bound to the root network.

than the rates that plant roots grow. As a trade-off to quicker actuation speeds, the absence of a rigid cell wall greatly reduces the maximum pressures that earthworms can exert, which are only on the order of $0.6\text{--}2 \times 10^5$ Pa (Ruiz and Or, 2018). This ultimately restricts the soil mechanical conditions that are suitable for earthworm activity.

Models for soil bioturbation by growing plant roots and earthworms burrowing

Both the penetration-cavity expansion burrowing of earthworms and tip extension of plant roots into soil can be described as local penetration processes, where soil is displaced and deformed radially about these biological surfaces. Recent models quantified the pressures required by earthworms and plant roots to form biopores in wet soils based on the mechanics of radial cavity expansion in an elasto-viscoplastic medium (Ruiz et al., 2017). More specifically, the model defines the radial stresses induced by either an earthworm's hydroskeleton or expanding root tissue at a cavity wall as σ_r (Ruiz et al., 2017). The minimum mechanical stress (pressure) required to expand a radial cavity in wet soil is given as:

$$\sigma_r(R_p) = P_L - 2s_u \ln\left(\frac{R_p}{r_c}\right) = s_u \quad (1)$$

where r_c [m] is the cavity radius, P_L [Pa] is the pressure at the cavity interface, R_p [m] is the radius of the elasto-viscoplastic interface (i.e., remote elastic effect), and s_u [Pa] is the soil shear strength. The ratio between the cavity zone and the inelastic zone converges to the ratio between the shear modulus of rigidity and the soil strength:

$$\left(\frac{R_p}{r_c}\right)^2 \rightarrow \frac{G}{s_u} \quad (2)$$

Fig. 3 Penetration-cavity expansion model for soil bioturbation (Ruiz et al., 2017) and (Dorgan, 2015). Example illustrates earthworm peristaltic motion that translates into penetration-expansion processes (a–c). Physical characteristics can be mechanically described by cavity expansion in wet soils (c), where the soil mechanical properties are linked to soil saturation state and texture class (d). Figure was adapted from Purves WK, Sadava D, Orians GH and Heller HC (2003) *Life: The Science of Biology: Volume III: Plants and Animals*. Macmillan.; Ruiz SA, Bickel S and Or D (2021) Global earthworm distribution and activity windows based on soil hydromechanical constraints. *Communications Biology* 4: 1–9.

where G [Pa] is the shear modulus of the soil. Substituting in the ratio in Eq. (2) into Eq. (1) determines the lower limit pressure required for cavity expansion:

$$P_L = s_u \left(1 + 2 \ln \left(\frac{R_p}{r_c} \right) \right) = s_u \left(1 + \ln \left(\frac{G}{s_u} \right) \right) \quad (3)$$

The resulting expression provides the minimum amount of pressure an earthworm or plant root would have to exert to expand a cavity radially in soil, based on the soil mechanical properties (Fig. 3d). Note that G and s_u are dependent on soil texture class and soil moisture status (Ruiz et al., 2017).

To consider the distinction between earthworms and plant roots, viscosity should be considered, as it takes into account the differences in their respective penetration rates ($1 \times 10^{-4} \text{ m s}^{-1}$ vs. $1 \times 10^{-7} \text{ m s}^{-1}$ respectively). Further distinctions can be found based on their respective pressure limitations. An earthworm's hydroskeleton is mechanically limited to a maximum pressure of $P_w = 2 \times 10^5 \text{ Pa}$ (Ruiz and Or, 2018). Thus, earthworms are mechanically impeded by soil conditions when $P_L \geq P_w$. Plant roots, may continue to grow in mechanically restrictive conditions by contrast, as $P_r = 2 \times 10^6 \text{ Pa}$. These constraining soil mechanical conditions are linked to the hydration status and texture of soil (Ruiz et al., 2017).

The resulting mechanical constraints on soil bioturbation have been used to outline global regions that permit earthworm bioturbation (Fig. 4). Furthermore, this mechanistic description also enables predictions for earthworm activity windows, which were found to be consistent with annual seasonal cycles. It is worth noting that there are auxiliary constraints that may also impede their biophysical activity such as water availability, soil pH, and temperature.

Fig. 4 Mechanically hospitable regions for earthworm activity (a) and activity time windows (b). The map in (a) illustrates minimum pressure required to expand a cavity in soil (limit pressure) associated with physiological pressure limitations of earthworms, highlighting regions that would impede earthworm activity in yellow to red. Activity windows in (b) illustrate the inverse correlation between limit pressure and monitored earthworm abundance in the United Kingdom. Figure adapted from Ruiz SA, Bickel S and Or D (2021) Global earthworm distribution and activity windows based on soil hydromechanical constraints. *Communications Biology* 4: 1–9.

Rodent excavation and burrowing activity

Burrowing activity by rodents, such as gophers and badgers, is another form of soil bioturbation. It is estimated that rodent populations alone dislodge 4–55 t of soil per ha annually (Table 1). Such displacement can produce 3–15 m³ of burrows per ha annually, depending on the relative abundance of different rodents. Under favorable conditions, gopher abundance can be as high as 125 per ha. These conditions appear to be proportionate to vegetated ground cover. Thus, rodent burrowing will have their most dominant impact in natural grasslands, then forests, and lastly in agricultural settings (Bocek, 1986).

Rodent burrow structures consist of openings to the soil surface, nesting regions, food storage sections, and feeding tunnels (often parallel to the surface). Tunnel depths are associated with several soil physical characteristics such as texture and water table height, however, they are also influenced by root penetration depth as plant roots are a primary source of food. Individual gophers burrow tunnels exceeding 150 m cumulative length, with up to one third of the tunnels being horizontal. Most of the burrowing length is dedicated to nesting compartments and tunnels to the surface (often in sections less than 1 m long). Nesting and storage chambers are often placed at greater depths (0.5–1 m depth), see Fig. 4. However, certain gopher species construct nesting mounds on the surface (Bocek, 1986; Hickman, 1977) (Fig. 5).

Rodent burrows result in tunnel sizes much larger than earthworm galleries, with gopher tunnels having mean radii of about 0.03 m (Vleck, 1981). The influence that they have on soil fertility is not immediately evident. The larger tunnel sizes are often associated with visible mounds on the surface. Initial tunneling activities may adversely impact vegetation by cutting roots and even main stems, causing an initial reduction in vegetation by as much as 20% (Grant et al., 1980). Despite these initial effects, evidence suggests that the soil re-worked by this activity becomes broken up and loosened, and decaying plant biomass becomes mixed with the impacted soil. These soils ultimately become more friable and richer in soil organic matter, which facilitates subsequent soil

Fig. 5 Diagram of gopher burrowing system. Highlighted are shallow and deep tunnels consisting of food compartments, nests, and drainage systems. Figure adapted from Hickman GC (1977) Burrow system structure of *Pappogeomys castanops* (Geomysidae) in Lubbock County, Texas. *American Midland Naturalist* 97: 50–58.

biological and physical functionality. Abandoned tunnels eventually collapse under gravity and rain fall, and gradually fill with material from the surface (Bocek, 1986). Consequently, the soil becomes more fertile through this loosening, as it permits greater air and water transport through the pore space. Lastly, the loosened soil enables better plant root soil penetration during root tip growth.

Depending on the behavioral group, rodents tunnel through soil using either their frontal claws (i.e., scratch-digging) or their strong incisor teeth (i.e., chisel-tooth digging) to loosen soil (Fig. 6) (Samuels and Valkenburgh, 2009). Loosened soil will then be pressed radially along the tunnel or displaced into regions of the system that are no longer in use (Grinnell, 2020). Limited studies have tried to mechanically quantify these activities by assessing the mechanics associated with the penetration of rodent incisors into soil (Ma et al., 2020). While previous studies have provided certain insights into some of the underlying mechanics associated with the burrowing activity (Ma et al., 2020), investigations with more rigorous experimental and modeling methodologies are needed.

Habitat formation and nesting activity in soil by miner bees

Miner bees are solitary bees that construct nests in the soil, preferring well drained conditions with soils comprised of moderately high silt and clay contents (Lybrand et al., 2020). As they feed on flower nectar and act as pollinators, their preferred habitats are in areas with abundant floral diversity (Rau, 1929). Despite being somewhat solitary, they maintain their tunnels neighboring other miner bees. These crowded villages may consist of 100–1000 burrows that the bees themselves have difficulty distinguishing. The tunnels accessing these burrows end in large “mud chimneys” or turrets that are visible above ground (Fig. 7a). While the exact purpose of the turrets is not clear, certain speculation suggests that these chimneys serve as land marks for returning bees (Rau, 1929). Turret sizes are about 0.005–0.01 m in diameter and vary in length (upwards of 0.06 m). Below ground, the tunnels are hollow, tortuous and hard to follow due to the closeness to other nests. They are not sealed by bees. Both tunnels and turrets contain greater concentrations of clay, which make them hard. Clay is also used deep in the tunnels by bees to form sealed compartments

Fig. 6 Mechanical description of badger teeth loosening soil. (a) simplified illustration of a badger skull with the incisor colored in tan. Skull image is adapted from Zagrai et al. (2019). (b) penetration of incisors in soil is reliant on soil internal friction. Note that some rodents also use their claws to scratch and dig through soil (Samuels and Valkenburgh, 2009). Figure is adapted from Ma Y, Wang H, Zhuang J, Qi H and Yu J (2020) Effects of bionic curves on penetration force under difference soils. *Applied Sciences* 10: 529.

Fig. 7 Miner bee tunnel characteristics and process. (a) Miner bee tunnels have chimney like turret structures that extend above their tunnels. Their below ground tunnels consist of compartments for eggs and pollen that can be sealed off by a dense soil plug. The process of creating tunnels requires bees to wet the soil (b) and subsequently dislodge moistened soil with their mouths (c). They will then carry dislodged soil out with their front legs (d).

that store pollen and eggs (Rau, 1929). This allows the bees to keep their tunnels open without worrying about intruders or harsh weather conditions.

The formation of below ground nests is an intricate excavation process that requires the bees to work through dense clay. Bees will transport water in their gullet extracted from mud puddles up to 5 m away from their tunnels, with a round trip journey taking 15–30s. Water is used to moisten hard clays in order to reduce their strength and rigidity (Fig. 7b). Once sufficiently soft, bees can then remove a mouthful of soil (Fig. 7c). They will subsequently carry removed soil with their front legs and back out of their nest to the opening with their hind legs (Fig. 7d). The soil is used to build and reinforce their chimney structures (Rau, 1929). Few studies have focused on the interplay between bee habitats and soil structure (Lybrand et al., 2020). It is likely that the nesting tunnels provide preferential flow pathways for water and extend oxygenated zones in soil. Chemical analysis found soils impacted by miner bee communities were rich in lipid like compounds, which may act to stabilize the tunnels. This would also provide organic matter to be cycled into the soil.

Current studies have yet to propose mechanistic models for soil bioturbation by miner bees, in particular soil mechanical limits for the dislodging process that occurs during the moistening and removal of soil mass. The transport of soil particles may have certain similarities to other soil dwelling insects. Certain elements of these processes will be elaborated next on the section for bioturbation by ants and termites.

Bioturbation by ants and termites in tropical and arid regions

While earthworms and plant roots play a prominent role in soil structure formation in temperate regions, other organisms dominate bioturbation in tropical and arid regions. Richness maps indicate that these regions are dominated by ant and termite bioturbation resulting from their tunneling activities during nest or gallery formation (Fig. 8) (Tuma et al., 2020). Sampling biases in these regions limit the amount of data on their activity, which makes it difficult to ascertain the direct impact and importance of ants and termites. However, there are a few studies that have reported the impact that these soil bioturbation agents have on soil structure.

The influence of ants and termites on soil structure and associated properties is somewhat similar to earthworm burrows and root channels. Ant and termite galleries and nests enhance water infiltration and soil aeration. Furthermore, these galleries also provide paths of least resistance for root growth. The spatial extent that a single gallery may influence may range from 13 to 50 m in

Fig. 8 Global richness maps of termites (top) and ants (bottom) replicated from Tuma et al. (2020).

radius from the location of a mound (De Bruyn and Conacher, 1990). While the formation of galleries may be similar, termites will incorporate organic constituents in their gallery formation. Mounds formed by termites act as a biological crust that protect the soil against water and wind erosion. Furthermore, this enhances soil aggregation by termites, which does not occur for ants (Jouquet et al., 2021). In the following, we outline models for termite mound physical functionality and the physical process involved in the construction of nests and galleries highlighting constraints to nest formation and rates of tunnel formation based on their excavation process.

Termite mounds physical functioning

Termites maintain favorable habitats in otherwise harsh warm conditions in arid and tropical regions by constructing large porous mound structures for controlling internal temperatures and humidity. Variations in termite mound morphologies can be attributed to heat and mass transport, and termites modify the mound shape in response to local odor concentrations (e.g., metabolic gases, pheromones, etc.) reflecting diffusion and airflow patterns. Temperatures in the mound are modulated by diurnal fluctuations and advection through the mounds caused by airflow. Models have been developed to understand these modulations based on physical principles. One model specifically considers three physical phenomena: temperature evolution based on the heat equation, with air flow regulated by Darcy's law, and odor transport based on diffusion-advection (Ocko et al., 2019). Steady state mound morphologies can be predicted based on physical non-dimensional parameters such as Peclet number, Biot number and relative mound thickness. Considering an average odor concentration at the mound walls of ϕ_c , a mound radius of R_m , and a mound height of h_m , then the surface area of the mound must be enough to balance the volumetric flux of odor generated inside the mound J (Fig. 9).

Fig. 9 Physical processes that drive morphological evolution of termite mounds as adapted from Ocko SA, Heyde A and Mahadevan L (2019) Morphogenesis of termite mounds. *Proceedings of the National Academy of Sciences* 116: 3379–3384. (a) Initial mound state and associated disjointed regions. (b) Response of heat profile and airflow under diurnal temperature fluctuations. (c) Odor profile which subsequently drives extension of the mound. (d) The updated mound morphology.

The flux can be given by

$$J = R_m^2 \phi_c D_{diff} / h_m, \quad (4)$$

where $D_{diff} [\text{m}^2 \text{s}^{-1}]$ is the diffusivity of the volatile odor. Thus, a mature mound at steady-state should have a radius described by:

$$R_c = \sqrt{\frac{J h_m}{D_{diff} \phi_c}} \quad (5)$$

The Peclet number (i.e., the ratio between advective and diffusive fluxes) is defined as

$$Pe = \frac{R_c (\kappa \alpha \rho g \Delta T)}{D_{diff} \eta} \quad (6)$$

where $\Delta T [\text{K}]$ is the diurnal temperature change, $\kappa [\text{m}^2]$ is the mound permeability, $\eta [\text{Pa s}]$ is the air viscosity, and $\alpha \rho g [\text{Pa m}^{-1} \text{K}^{-1}]$ is the buoyancy parameter. Similarly, the Biot number (i.e., ratio between thermal conduction and convection) is defined as

$$Bi = \frac{\sqrt{\tau D_T}}{R_c} \quad (7)$$

where $\tau [\text{s}]$ is the diurnal period and $D_T [\text{m}^2 \text{s}^{-1}]$ is the thermal diffusivity. Lastly, the relative thickness is given by

$$Th = \frac{h_m}{R_c} \quad (8)$$

Termites will adapt their mound's morphological trends and features such as sphericity and volume based on these non-dimensional values, thus presenting a physical rationale for mound designs (Fig. 10). While these mounds can explain how termites modulate the conditions in their habitats, other mechanisms associated with soil physical conditions may help to explain their global distributions.

While temperature and airflow play an important role in the termite nest structure, regulating moisture conditions is also critical for their habitats. A cross sectional view of a termite nest (Fig. 11a) elucidates several conduit structures and galleries that play a role in guiding soil moisture and vapor through the nest, regulating the nest humidity (Turner, 2006). These structures give rise to the moisture fluxes in and out of the nest (Fig. 11b) (Turner, 2006). Fluid is drawn inward from the adjacent soil based on differences in matric potential described by

$$J_{n,s} = K_h (\Psi_s - \Psi_n) \quad (9)$$

where $K_h [\text{m s}^{-1} \text{Pa}^{-1}]$ is the hydraulic conductance of the soil, $\Psi_s [\text{Pa}]$ is the soil water potential, and $\Psi_n [\text{Pa}]$ is the water potential of the nest. Evaporation of the nest is based on the difference between the nest and atmospheric humidity (based on partial pressures) given by

$$J_{n,a} = K_v (\Delta p H_2 O) \quad (10)$$

Fig. 10 Termite mound morphologies according to physical principles as adapted from Ocko SA, Heyde A and Mahadevan L (2019) Morphogenesis of termite mounds. *Proceedings of the National Academy of Sciences* 116: 3379–3384. (a) Termite mound absolute size increases with relative thickness (Th), but its sphericity reduces with increasing Peclet number (Pe). (b) Mounds are more bottom heavy for low Biot (Bi) numbers, cylindrical for medium Biot numbers and top heavy for high Biot numbers.

Fig. 11 Termite mound architecture and its role in regulating moisture as adapted from Turner (2006). (a) Termite nest and mounds consist of several conduit, chimney and channel structures that conduct and transport water in the form of liquid moisture in the soil pore space as well as water vapor. (b) These conduits serve as the basis for a model describing the water flux balance in the nest, considering the transport of water into the nest from adjacent soil, the transport of water out of the nest via evaporation, and the active transport of moisture in and out of the nest by targeted amendment of nest properties. (c) Conceptual functioning of the model considering precipitation above the mound and water permeating along adjacent permeable routes and (d) movement of moisture through the nest.

where K_v [$\text{m s}^{-1} \text{Pa}^{-1}$] is the mound's vapor conductance and Δp_{H_2O} [Pa] is the difference between the partial pressure of vapor in the nest and the atmosphere. Water can be further conveyed into the nest from the deep soil or onto the surface of the nest by the transport of damp soil, which helps achieve a target nest moisture content, Ψ_n^* . These fluxes are described and regulated by the expression:

$$J_{n,n^*} = \varepsilon(\Psi_n - \Psi_n^*) \quad (11)$$

where ε [$\text{m s}^{-1} \text{Pa}^{-1}$] is a regulating error signal that reflects the difference between the moisture of the nest Ψ_n [Pa] and the “target” nest moisture Ψ_n^* [Pa]. A conceptual description of the water movement around and subsequently through the nest can be seen in Fig. 11c and d, which illustrate the regulation process of soil moisture through the nest.

The construction of the fluid conduits in and around the mounds play a role in augmenting soil around the termite mounds themselves. This impacts the water cycle and local hydrology near the mound locations. Ultimately, the construction of the termite nests acts to enhance soil water retention.

Biophysical modeling of granular transport by ants and termites

Bioturbation by ants and termites displaces soil by carrying away discrete soil aggregates or sand grains of size D with their mandibles of size M (Fig. 12a) (Espinoza and Santamarina, 2010). Models describing how harvester ants manually transport soil based on a particle removal model showed that ants used different approaches to remove particles depending on grain size relative to their mandible width and soil water content (Fig. 12b). For fine textured soils, ants remove soil and form loose aggregates at low moisture conditions. When soil moisture is higher, ants are forced to pull fine particles in several successive grabs until they can form a stable aggregate. When aggregates reach a diameter of roughly 3 mm, ants are able to transport them (Espinoza and Santamarina, 2010).

In contrast to finer soil particles, dry coarse particles such as sand grains can be handled by ants in single grabs. However, the number of dry coarse soil particles that can be transported in a single grab is limited by friction and by capillarity forces. Modeling aggregation of particles is based primarily on consideration of capillarity and van der Waals forces. The weight of a transportable soil aggregate is affected by capillary forces between spherical particles with diameter d [m], expressed as:

$$F_c = \frac{\pi}{2} \gamma d \left(2 - \left(\frac{8}{9} G \theta_m \right)^{\frac{1}{4}} \right) \quad (12)$$

Fig. 12 Granular transport process of ants and termites adapted from Espinoza DN and Santamarina JC (2010) Ant tunneling—A granular media perspective. *Granular Matter* 12: 607–616. (a) Ants are constrained by a soil aggregate of a size D , as this cannot exceed their mandible size M . Aggregate sizes are made up of smaller particle sizes d , which are aggregated depending on their particle size. (b) Soil physical constraints depend on texture class, moisture content, electrical forces (F_e) and capillary forces (F_c). Overly dry soils rich in silt and clay may be too strongly bound for removal due to electrical forces. Dry sand may be removed, but it may require several passes to move multiple particles. Mildly wetted soils may have sufficient capillarity for optimal movement. Overly wet silt and clay may be too heavy to carry. If soil is too wet, then there might not be sufficient binding.

where γ [N m^{-1}] is the surface tension, G [$\text{kg}_{\text{grain}} \text{m}^3_{\text{water}} \text{kg}^{-1} \text{m}^{-3}_{\text{grain}}$] is the specific gravity of a mineral grain, and θ_m [$\text{kg}_{\text{water}} \text{kg}^{-1}_{\text{grain}}$] is the gravimetric water content (Espinoza and Santamarina, 2010). For small particles, van der Waals forces may become dominant, which are estimated as:

$$F_E = \frac{A_h}{24h^2}d \quad (13)$$

where A_h ($=0.83 \times 10^{-20}$ J) is the Hamaker constant for quartz-water-quartz, and h [m] is the inter-particle spacing between the two particles of size d [m] (Espinoza and Santamarina, 2010). Besides the mandible size constraint, ants are constrained by the weight of a particle that they can carry. The weight is given as:

$$F_w = \frac{\pi}{6}d^3Gg\rho_w \quad (14)$$

where g [$=9.81 \text{ m s}^{-2}$] is the gravitational acceleration, and ρ_w [$=1000 \text{ kg}_{\text{water}} \text{m}^{-3}_{\text{water}}$] is the density of water (Espinoza and Santamarina, 2010). The maximum weight an ant can lift is on the order of $3\text{--}6 \times 10^{-3}$ N, thus there is a balance between particle size and weight that is dependent on aggregate moisture content and particle sizes. This affects the tunneling rates of ants.

Considering the processes above, ants can construct biopores more easily under drier soil conditions (prevailing in arid regions), which is in stark contrast with conditions favored by earthworm bioturbation in wet soil. These details are consistent with findings that ants and termites are dominant bioturbation agents in semi-arid and arid regions, not only because earthworms are mechanically prohibited from these regions, but the physical process that ants and termites rely on is facilitated by drier conditions with coarse grained soil.

Conclusions

Bioturbation of soil arises from plant roots, insects and mammals. The underpinning penetration-cavity expansion bioturbation model associated with growing plant roots and tunneling earthworms (penetrators) provides a mechanistic model to describe the formation of biopore networks under different climatic conditions and soil types. This model can also be useful in outlining limitations for below ground activity by earthworms, explaining their reduced abundance in arid and tropical regions. Excavation of soil by ants and termites contributes to soil structure maintenance in arid and tropical regions where earthworm activity is limited. The environmental selection of ants and termites can be explained by biophysical models for their granular soil dislodging and transport activities, which are easier in dry conditions and coarse soils. Future studies may be able to extend these models and formulate similar constraint maps as those that exist for global earthworm distributions (Ruiz et al., 2021).

Excavation activity by larger rodents is complex in terms of short term (adverse) impacts on existing vegetation and long-term contributions to soil health. The available mechanistic and ecological models remain sketchy, and more work is needed to assess the effects of rodent bioturbation on ecosystem functioning. Understanding mechanistic biophysical principles associated with bioturbation processes can help quantify conditions that promote and restrict subterranean activity by different organisms. Empirical evidence suggests a significant impact of soil bioturbation on mechanical and transport properties of soil, with effects on ecosystem functioning and soil health. Therefore bioturbation should be incorporated in modern Earth system models of near surface processes. Recent studies highlight the importance of bioturbation in landscape formation processes (e.g., tree throw (Gabet et al., 2003)) and in soil alteration and production, but the modeling lags behind.

Abstract

The biophysical interactions between soil and vegetation are discussed from a mechanical and hydrological perspective. How these interactions impact the stability of soil on slopes and protect against shallow landslides is presented, along with a brief outline of models used to calculate the reinforcing effects of roots on soil, and how these models have been derived in the last half-century. Methods are discussed for measuring root-permeated soil shear strength in the field and laboratory. Future challenges for research are outlined, and include the difficulties encountered when integrating large roots and the architecture of complex root systems into mechanical models, as well as scaling up to the landscape level.

Key points

- Plants with numerous, strong roots increase soil shear strength
- Direct soil-root shear tests quantify reinforcement, but need a small normal force
- Plant species mixtures enhance both soil mechanical and hydraulic properties.
- Root system architecture should be better integrated in mechanical models

Introduction

Plant roots reinforce soil against mass movement of substrate through a mixture of physical and chemical processes. These processes are controlled by the functioning of plants and microbes that are impacted by diverse root traits, as well as by environmental factors, including soil type, soil water content, soil cohesion and pH. Soil reinforcement mechanisms have been extensively reviewed in the last two decades, mostly from the geotechnical perspective of improving slope stability against shallow landslides (Giadrossich et al., 2017; Stokes et al., 2009; Fig. 1), but also with the aim of understanding fundamental processes related to ecosystem functioning (Freschet et al., 2021).

Most studies on plant root systems and soil reinforcement have focused on measurements of soil shear strength at near-saturation levels, root mechanical properties and root area ratio (RAR), the fraction of a plane of soil occupied by roots. These data are then used in models that calculate the contribution of vegetation to slope stability. Nearly all studies find that plant species, which have roots that are strong in tension and a large RAR, increase soil shear strength (Freschet et al., 2021). This knowledge can be used in defining planting and management schemes applicable to natural and artificially constructed slopes, a practice that originated 4000 years ago for the management of flood waters in China, and is now common practice in many countries worldwide.

In this chapter, we focus on the fundamental mechanisms driving soil reinforcement and how vegetation shapes these processes. We explain the factors that govern soil shear strength and how plant root systems physically interact with soil to alter shear strength. We review the most common methods for measuring soil and root physical properties related to soil reinforcement, and conclude with an update on the most recent models used to estimate the role of vegetation in stabilizing slopes.

Soil shear strength

Soil shear strength (τ) is defined as the resistance to deformation by the action of tangential (shear) stress. Soil shear strength is made up of cohesion between particles and resistance to particles sliding over each other due to friction or interlocking. Cohesion is composed of true cohesion and apparent cohesion. True cohesion is a function of soil mineralogy and results from chemical bonds between particles. Apparent cohesion, however, is determined by water tension within the soil and is strongly influenced by water

content (Flerchinger et al., 2005). Additional cohesion from plant roots can also enhance soil shear strength as roots are stronger in tension than soil and add reinforcement as soil is deformed during shear. Soil shear strength and the contribution of roots to shear strength are usually measured via direct shear tests (Fig. 2A) and triaxial tests (Fig. 2B).

Direct shear tests

Direct shear tests are commonly employed in geotechnical engineering practice and research to determine the shear strength of a soil. The test is generally performed in a container consisting of two halves, where one half is moved relative to the other (Fig. 2A). The

interface between two boxes acts as a failure plane, where the sample is sheared - not at its weakest plane. A normal force is applied at the surface of the sample to induce a normal stress (σ_n) at the failure plane, and a horizontal force is applied to one half of the box.

A direct shear test can be performed as either displacement-controlled (i.e., the container is pushed at a constant displacement rate while measuring the force required) or stress-controlled (i.e., the force is increased at constant increments and displacement is recorded). ISO 17892-10 (International Organization for Standardization, 2018) or ASTM D 3080 (ASTM International, 2012) standards provide guidelines for conventional direct shear testing. Since the pioneering studies on soil reinforcement by Wu et al. (1979) or Waldron and Dakessian (1982), direct shear testing is one of the most frequently used methods to measure the shear strength of root-permeated soils. Tests can be performed either in situ (or in the laboratory (Mickovski and van Beek, 2009; Ghestem et al., 2014; Yildiz et al., 2019)). In situ tests are the most realistic in terms of field conditions (Fig. 2C): roots are fully embedded in undisturbed soil and anchored below the potential shear surface, and soil can be saturated before the test begins. However, in situ tests are time consuming and are usually performed on a flat ground surface because of complications with testing on a slope. Additionally, as soil and root system characteristics vary spatially and temporally, a large number of measurements must be performed across a site and at different points in time, to assess which areas are the most susceptible to shallow landslides. To overcome these difficulties, Meijer et al. (2019a) adapted a garden corkscrew weeder so that peak soil shear strength could be measured rapidly in the field. This method measures the resistance against pull-out extraction of a cylinder of (rooted) soil caught within the screw and can be used on steep slopes.

The aforementioned standards define limitations on maximum particle size of a soil that can be tested in direct shear testing. ASTM D-3080 limits the maximum particle size to one tenth of the shear box width and one sixth of the specimen height. A standard commercially available direct shear apparatus (mostly capable of testing square samples of 60×60 mm or circular samples of 60 mm in diameter) cannot accommodate soils with larger-size particles for testing. As vegetated soils are generally procured from field sites, they can contain gravel-sized particles. Furthermore, the root diameters to be tested in a direct shear apparatus can also exceed the size limitations of the standards. In laboratory studies, due to these size limitations and the importance of monitoring hydrological aspects during testing, many studies investigating the shear strength of root-permeated soils are conducted with non-conventional testing devices (Yildiz et al., 2019).

Root-permeated samples to be tested in a laboratory direct shear apparatus are generally prepared in two ways. The first approach is to prepare a reconstituted specimen that has segments of roots taken from a living plant inserted into the shear box. This approach enables the control and measurement of parameters related to root morphology, such as diameter, angle, length and tortuosity. However, it is clearly not representative of the natural growth state of roots in undisturbed soil. The second technique is to grow plants in a shear box either under controlled, e.g., in a growth chamber or glass house (Yildiz et al., 2019), or monitored conditions, e.g., in the field with continuous monitoring of meteorological parameters (Veylon et al., 2015), (see Table 4 in Freschet et al. (2021) for a review of root system characteristics and shear strength of root-permeated soil, in comparative studies with several plant species per study). Much more realistic conditions prevail, especially with regard to root anchorage in soil and the root-soil interface; however there is minimal information about the number of roots, root area ratio, or any other root characteristics before the test commences.

Direct shear tests are performed under the application of a load perpendicular to the shearing plane. Tests are generally performed for at least three levels of normal load to be able to calculate shear strength parameters. Considering the typical depth of a shallow landslide, i.e., 1.0–2.0 m, (Norris et al., 2008), the normal load applied during direct shear testing of root-permeated soils should be comparable to the overburden pressure that the soil experiences at shallow depths. Therefore, in comparison to conventional shear tests applied in geotechnical engineering, generally much smaller pressures should be employed, taking into account only the weight of soil above the potential shear plane and the weight of vegetation (Veylon et al., 2015).

Triaxial testing

An alternative method to determine the shear strength of soil is via triaxial testing (Fig. 2C). These tests are performed on cylindrical specimens, usually with a height to diameter ratio of 2:1. The specimen is contained in a cell, which is filled generally with water, and is subjected to an all-around radial pressure, i.e., cell pressure. An axial load is applied on the specimen until failure is observed, while the deformations are measured (Terzaghi et al., 1996). Either consolidated (i.e., excess pore water pressure in the sample generated due to loading is dissipated) or unconsolidated (i.e., sample is tested before the dissipation of the excess pore water pressure) samples can be tested under drained or undrained conditions. Four main stress paths, namely axial compression, axial extension, lateral compression, and lateral extension can be applied on a sample. Triaxial testing has various advantages over direct shear testing, which can be summarized briefly as follows:

- Sample fails at the weakest plane,
- Easier to monitor deformations, and calculate strains,
- More realistic representations of stress state under field conditions can be generated,
- Samples can be tested under various stress paths (e.g., extension or compression) and conditions (e.g., drained and undrained).

Triaxial testing on root-permeated soils is much rarer than direct shear tests mainly due to the complexity of the procedure. However, it is sometimes inevitable as the nature of the problem and the conditions identified in the field dictate the use of triaxial testing on root-permeated soils. For example, Foresta et al. (2020) investigated the volume collapse of pyroclastic soils in Southern

Table 1 Details of studies using triaxial testing on root-permeated soils.

Test	Plant species	Soil Sample Size: Height, Diameter [mm]	Confining pressure [kPa]	References
Consolidated Undrained	<i>Alnus incana</i>	140.0, 70.0	50, 75, 100	Zhang et al. (2010)
Consolidated Drained	<i>Robinia pseudoacacia</i>	80.0, 39.1	100, 200, 300, 400	
Unconsolidated Undrained	<i>Atriplex canescens</i> , <i>Caragana korshinskii</i> , <i>Zygophyllum xanthoxylon</i> , <i>Nitraria tangutorum</i> , <i>Lycium chinense</i>	125.0, 61.8	10, 20, 30, 40	Hu et al. (2013)
Consolidated Drained and Consolidated Undrained	Poaceae	79.3, 36.4	10, 30, 50	Foresta et al. (2020)

Italy under fully saturated undrained conditions, and so performed consolidated drained and undrained triaxial tests on samples planted with grasses, to assess the effects of roots on the occurrence of static liquefaction. Only a few similar studies exist that have used triaxial testing (see Table 1), and they follow the 2:1 aspect ratio of cylinder height to diameter suggested by various standards. A minimal number of studies tested soils at confining pressures comparable to the stress state of a soil element at a shallow depth.

How vegetation impacts the hydraulic properties of soil

In a soil with a large water content, the pore water pressure can increase and reduce soil shear strength. Pore water pressure is the pressure (isotropic normal force per unit area) exerted by the fluid phase, where pores are filled or partially filled with water and is averaged over a representative elementary volume of soil containing many pores, rather than an individual pore. If vegetation is present and actively growing (i.e., not in seasonal dormancy), water can be removed via evapotranspiration, i.e., the combination of evaporation from the soil and plant transpiration. The forces between air, water, and soil particles lead to changes in matric suction. Matric suction, or negative pore water pressure, is the free energy change in a unit volume of water, when isothermally transferred from the soil water state to the free water state and is defined at the soil-water-air representative elementary volume. Matric suction is therefore the pressure dry soil exerts on the surrounding material to equalize the moisture content in the overall block of soil and it is estimated as the difference between pore air pressure (u_a) and pore water pressure (u_w). Negative pore water pressures produce matric suction and greater shearing resistance. This process is termed hydrological or hydric cohesion.

When soil is saturated on a vegetated site, positive pore-water pressures reduce soil shear strength and can also produce uplift pressure (u_z). Hydrostatic uplift (also known as uplift pressure), is an upward pressure applied to a structure (such as vegetation), that has the potential to raise it relative to its surroundings. Hydrostatic uplift can be problematic if it is greater than the weight of the structure (e.g., plant mass) exerted downwards. The downward weight of the plant is therefore reduced, and mechanical integrity of the soil and vegetation can be compromised (Liu et al., 2021).

Vegetation also causes changes in soil hydrological conditions through the interception of precipitation by the canopy, and channelling of rainfall down stems and along roots. Furthermore, as roots grow through soil, they create channels - also termed biotic macropores (Ghestem et al., 2011) - along which water can flow (Fig. 3). In addition to forming biotic macropores, plant roots are major drivers of soil structure formation through aggregation at the root-soil interface. This phenomenon occurs due to hydrological stresses from root-water uptake, mechanical deformation from root growth and the secretion of organic compounds that provide substrate for microorganisms and actively bind soil particles. Mycorrhizal fungi are particularly important soil organisms that are associated with roots, soil aggregation and stability. Additionally, plant roots can promote slope drainage by creating macropores and functioning as hillslope-scale preferential flow paths that by draining subsurface water away from potentially unstable sites reduces pore-water pressure. However, when root channels converge or when subsurface flow abruptly terminates in the slope (e.g., if roots cannot penetrate bedrock and growth accumulates over the bedrock surface), water pressure may concentrate in critical zones, thus promoting localized zones of instability (Ghestem et al., 2011). The role of coarse roots (with a diameter > 2 mm) on preferential flow is therefore highly variable, whereas finer roots (with a diameter < 2 mm) have a more consistent effect on infiltration processes via matrix flow, i.e., uniform flow through fine pores. However, many fine roots can also block pores and greatly reduce hydraulic flow. It is therefore advisable to promote species mixtures on a vegetated slope, so that a range of root branching densities (Freschet et al., 2021) and pore sizes throughout the soil profile will enhance infiltration and drainage processes (Nespoulous et al., 2019).

How plant roots reinforce soil mechanically

Mohr-Coulomb theory is a mathematical model used to define the shear strength (τ) of soils at different effective stresses. The generalized form of the Mohr-Coulomb failure criterion using effective stress parameters can be expressed as follows (Lu and Likos, 2006):

Fig. 3 (A) Macropores (channels formed after roots have died and decayed) in a silty loam and (B) water stained with Brilliant Blue FCF dye flowing along and around a live root, but next to a root where no stained water was observed, demonstrating the highly variable nature of preferential flow processes around coarse roots on vegetated slopes. (A) Reproduced with kind permission from Ghestem M, Sidle RC, and Stokes A (2011) The influence of plant root systems on subsurface flow: Implications for slope stability. *Bioscience* 61: 869–879; (B) reproduced with kind permission from Nespoulous J, Merino-Martin L, Monnier Y, Bouchet DC, Ramel M, Dombey R, Viennois G, Mao Z, Zhang J-L, Cao K-F, le Bissonnais Y, Sidle RC, and Stokes A (2019) Tropical forest structure and understorey determine subsurface flow through biopores formed by plant roots. *Catena* 181: 104061.

$$\tau = c' + (\sigma - u_a) \tan \phi' + (u_a - u_w) \tan \phi^b \quad (1)$$

where c' is cohesion, σ is the normal stress, u_a is the pore air pressure, u_w is the pore water pressure, ϕ' is the internal friction angle, and ϕ^b is an additional friction angle to express the contribution of matric suction to shear strength in the partially saturated state. When soil is saturated, Eq. (1) simplifies to:

$$\tau_s = c' + (\sigma - u_w) \tan \phi' \quad (2)$$

In the 1970s, pioneering modelling approaches incorporated the action of plant roots into Mohr-Coulomb theory (Waldron, 1977; Wu et al., 1979), and they were based on the equilibrium of forces acting on a soil element permeated with roots. One of the key assumptions of such models is the full mobilization of root tensile strength as the root-soil is sheared and deformed (Fig. 4A).

As the soil is sheared, roots are stretched and pulled out of the soil, and subjected to a tensile force that can be divided into two components, acting in the tangential and normal directions. Long, well-anchored roots will increase pull-out resistance up to a critical root length, above which roots will break in tension instead of slipping out of the soil. Roots can also slip out of soil if the tensile stress in the root is greater than the bonding resistance between the soil and the root (Fan, 2012). However, the root failure type (breakage or slippage) was not considered in these pioneering models. The shear strength of the root-permeated soil (τ_r), can be expressed as follows:

$$\tau_r = c' + (\sigma' + t_r \cos \theta) \phi' + t_r \sin \theta \quad (3)$$

where θ is the angle between the vertical axis and the root after deformation, and t_r is the tensile stress on the root (Eq. 6). By substituting the shear strength of the soil at the saturated state, τ_s , into Eq. (3), we can define τ_r as:

Fig. 4 Intact and deformed shape of roots crossing a shear plane during deformation. an initially (A) perpendicular and (B) inclined root segment. Modified from Gray DH and Ohashi H (1983) Mechanics of fiber reinforcement in sand. *Journal of Geotechnical Engineering* 109: 335–353.

$$\tau_r = \tau_s + t_r(\sin\theta + \cos\theta\phi') \quad (4)$$

If an initially inclined root is deformed until an angle ψ is reached (See Fig. 4B), Eq. (5) becomes (Gray and Ohashi, 1983):

$$\tau_r = \tau_s + t_r[\sin(90 - \psi) + \cos(90 - \psi)\phi'] \quad (5)$$

Considering multiple perpendicular roots of various diameters passing through a potential failure plane, t_r can be calculated as:

$$t_r = \sum_{i=1}^n T_r^i \frac{A_r^i}{A} \quad (6)$$

where T_r^i is the tensile strength of the roots of diameter class i , A_r^i is the cross-sectional area of the roots of diameter class i , and A is the area of the shear plane. Root tensile strength is calculated as the force required per cross-sectional area of the root to cause failure, either through breakage or non-reversible deformation (see Giadrossich et al. (2017) for methods to measure tensile strength). Meijer (2021) proposed the use of a cumulative and continuous root diameter distribution instead of diameter classes, as information is lost concerning their real diameters, if roots are sorted into separate diameter classes. Wu et al. (1979) argued that the additional strength due to roots has the “characteristics of cohesion,” and the term “additional cohesion due to roots” (c_r) was coined, which can be generalized in Eq. (7).

$$c_r = k' T_r RAR \quad (7)$$

where the ratio A_r/A in Eq. (6) is denoted as RAR (root area ratio). Wu et al. (1979) suggested that the term $(\sin\theta + \cos\theta\phi')$ in Eq. (5) is insensitive to a range of values for root angle (θ , Fig. 4A) and effective internal friction angle of the soil (ϕ'). Also, the effects of roots on soil internal friction angle are variable and poorly understood (Veylon et al., 2015). Therefore, Wu et al. (1979) provided an average value of 1.2 as k' to substitute in Eq. (7). However, subsequent studies have shown that substituting 1.2 for k' in Eq. (7) generally overestimates the additional cohesion from roots, and alternatives to k' have since been suggested (see Mao (2022) for a review). One source of this overestimation is the mobilization of tensile strength of the roots and shear strength of soil. Fannin et al. (2005) demonstrated one isolated in situ direct shear test displaying two peaks in the shear stress - strain behavior and attributed the second peak to the presence of roots. Pollen et al. (2004) also noted that peak shear stress of soil and tensile stress of roots occurred at different displacements, and root strength may not be fully mobilized before failure. Therefore, Cohen et al. (2011) suggested that a simple addition of the strength of both components of the root-soil matrix would result in an overestimation.

As a result of these investigations, a new type of model was developed that accounts for variability in root diameter and tensile strength of a bundle of roots crossing a shear plane, where root failure is more likely to be progressive than simultaneous and roots can either break or slip out of soil during failure (Waldron and Dakessian, 1982). To simulate this progressive root failure, Pollen et al. (2004) examined an algorithm used in materials science called the Fiber Bundle Model (FBM). FBMs consider the sharing of load or energy over a bundle of roots that differ in size and material properties and a range of FBM models are now available for estimating c_r (Fig. 5 (Cohen et al., 2009), see Mao (2022) for a review). The order of progressive root failure can now be modelled by determining the critical displacement at which roots slip or break (Cohen et al., 2011), thereby simulating more effectively the failure of the soil-root matrix in shear tests (Fannin et al., 2005).

To correct for the over estimation of c_r in the model by Wu et al. (1979), a factor, k'' was suggested by Preti (2006), and is the ratio of c_r estimated by a FBM to that estimated in the Wu et al. (1979) model, based on the same root bundle. Several studies used a constant for k'' (or as a product of k'' and k') whereas others quantified k'' based on field data (Bischetti et al., 2009). Meijer (2021) simulated the variation of k'' as a function of load-sharing laws, root tensile strength and diameter variation, therefore enabling FBM users to quickly select a value for k'' depending on their needs. Typical values of c_r vary from 1 to 25 kPa depending on the type of soil and vegetation, and assumptions made in model development (see Table 5-2 in Norris et al., 2008, for typical values of c_r). Although values >100 kPa can be found in the literature, they are often derived from measurements close to the soil surface, where it is unlikely that soil failure will occur in shear.

Although much research has focused on the contribution of plant roots to soil cohesion, studies have usually focused on the inclusion of thin roots (< 10 mm in diameter) that are mostly subjected to tensile loading and so can be incorporated into the modelling framework described above. However, the impact of larger and stiffer roots that act in bending and compression has rarely been considered, although studies are now beginning to stress the importance of introducing these elements into slope stability models (Giadrossich et al., 2019). More detailed investigations into the effect of large, structural roots on slope stability, and the way root systems are designed in terms of architecture (Ghestem et al., 2014; Meijer et al., 2019b), are needed to close this knowledge gap. Also, the geometrical design of a root system, for example, branching intensity, will impact soil reinforcement as the presence of branches counteracts potential slippage between the soil and roots, allowing the mobilization of larger axial forces within the root (Meijer et al., 2019b). One way forward is through the use of scaled-down models of 3D root system architecture in geotechnical centrifuges (Zhang et al., 2020). Geotechnical centrifuges allow the testing of materials such as soil and rock, that have non-linear mechanical properties that depend on the effective confining stress and stress history. The centrifuge increases g-forces on the physical model, to produce identical self-weight stresses in the model and prototype. Zhang et al. (2020) successfully applied this technique to scaled down (1:20) physical models of tree root architecture (using real data and obtained via 3D printing). Through a series of tests in normal and elevated gravity conditions, Zhang et al. (2020) were able to determine the impact of soil moisture and root system architecture on the resistance of models to being pushed over laterally (considered as a proxy of loading

Fig. 5 During (A) a shallow landslide or soil failure in tension, plant roots are stretched, broken or can slip out of soil. In (B) Fiber Bundle Models (FBM), roots are modelled as a cluster of elements subjected to tensile forces. FBMs consider the sharing of load or energy over the modelled bundle of roots, that differ in size and material properties. (C) The modelled failure of roots is not simultaneous, reflecting field conditions. due to debris flow or wind). Although complex and costly, centrifugal technology will help our understanding of plant anchorage and soil failure processes, as well as validating the integrity of numerical soil reinforcement models.

Different types of models have been formulated over the years to predict landslide hazard at the slope level (see Murgia et al. (2022) for a review). Usually, an estimation of the Factor of Safety (FoS, i.e., the ratio of resisting forces to driving forces), based on physical data of soil and vegetation properties is calculated (Norris et al., 2008). A slope is considered to be stable if the FoS is > 1.0 . Engineered slopes are generally designed to have a FoS between 1.2 and 1.4 (Norris et al., 2008). Natural slopes have highly variable FoS depending on their geological and engineering properties. Studies that estimate FoS help explain why a slope has failed locally, but upscaling slope stability models to the landscape level is a challenge, partially because of a lack of suitable data to evaluate models, the challenge of selecting realistic input data in a heterogeneous environment, and also because of a lack of understanding of biophysical processes at different scales. There have been few attempts to model the influence of vegetation on slope stability over a landscape. However, the recent availability of accessible databases and techniques such as airborne LiDAR (Light Detection and Ranging) for assessing vegetation, makes it easier to obtain reliable vegetation, soil and hydrological input data. Similarly, the use of cutting-edge methods such as sediment source fingerprinting, that differentiates the properties of soil from different sources, (using e.g., signatures such as elemental geochemistry, radionuclides or environmental DNA in soil (Frankl et al., 2022)), would allow the investigation of complex and often poorly understood relationships between vegetation cover, substrate mass movement and geomorphological response at the catchment scale. Understanding, modelling and predicting mass movement processes over time and space in a vegetated landscape is one of the next major challenges for soil and plant biophysicists.

Outlook

Plant roots have a large impact on soil stability, operating at scales from individual aggregates up to the landscape. Changes to land management away from natural systems with perennial root systems, to areas temporally devoid of vegetation due to agriculture, forestry, construction or land degradation, have resulted in soils that are much more mechanically weak, and hence susceptible to landslides or other forms of instability. There is great scope to use vegetation to improve the physical stability of soil by the action of

plant roots, as has been observed in major restoration projects such as on the Loess Plateau in China. Geotechnical engineering projects can also replace nails, piles or concrete facings with vegetation to stabilize slopes, providing a green solution that is also cost-effective. The uptake of such approaches, however, has been limited by the trust in available predictive models and uncertainties caused by the interaction between soil, plants and weather.

Abstract

Salinity has become an increasing threat to soil physical properties due to drought and water shortages. There are impacts of salinity on plants due to osmotic impacts on soil pore water, and to soil water flow and transport from soil solution-soil matrix interactions. As the soil solution sodium adsorption ratio increases, the effect of salinity-induced, soil solution-soil matrix interactions on flow and transport worsens, as both soil solution concentration and capillary pressure head decrease. In finer textured soil, particularly those with smectite clay, pore structure changes exacerbate the impacts from salinity due to swelling, when sodium salts are present. This article provides background theory and a case study for soils irrigated with low-quality water.

Key points

- A shortage of rain and water resources in semi-arid and arid zones necessitates the use of low-quality water (LQW) such as saline water and treated sewage water (TSW) for irrigation
- Use of LQW for irrigation may accelerate contamination or salinization of soils and aquifers underneath irrigated regions
- Quantitative field-scale descriptions of chemical transport in the unsaturated zone are essential for basic understanding of LQW transport in near-surface geological environments, and for assessing reliably the threat posed by using LQW for irrigation to these environments
- Quantitative description of LQW transport requires the coupling of the flow to the transport through the dependence of the soil hydraulic properties on the solute concentrations.

Units and Nomenclature

a_i ($i = 1$ to 4)	Coefficients in Eqs. (3), (5) and (6) [dimensionless]
A_s	Specific surface area [$\text{cm}^2 \text{g}^{-1}$]
A_d	Specific surface area for adsorption [$\text{cm}^2 \text{g}^{-1}$]
A_e	Specific surface area for exclusion [$\text{cm}^2 \text{g}^{-1}$]
B	Half distance between two adjacent tactoids [cm]
$B(\text{Eq. 2})$	$kLTC_0/10^3(R + 1)$ [erg cm^{-3}] ($1 \text{ erg} = 1 \text{ g cm}^2 \text{ s}^{-2}$)
$C_{(.)}$	Concentration of the ion (.) [meql^{-1}]
C	$\text{can} + C_{\text{Ca}}$ [meql^{-1}]
$c_{(.)}$	Molar concentration of the ion (.) [mol l^{-1}]
C_0	$c_{\text{Na}} + c_{\text{Ca}}$ [mol l^{-1}]

d	Position of the mid-plane between two adjacent tactoids [cm]
D	The dielectric constant of water [dimensionless]
E_f	Elution factor [dimensionless]
F	Faraday constant [2.893×10^{11} esu meq ⁻¹] (1 esu = 1 g ^{1/2} cm ^{3/2} s ⁻¹)
G	$(8\pi C_0 Le^2 / 10^3 DkT)^{1/2}$ [molecules electron ⁻¹ cm ⁻¹]
h	Capillary pressure head [cm]
h_b	Air entry value of h [cm]
i, j	Indices [dimensionless]
k	Boltzmann's constant [1.38×10^{-16} erg deg. ⁻¹ molecule ⁻¹]
K	Hydraulic conductivity [cm s ⁻¹]
K^r	Relative hydraulic conductivity [dimensionless]
ℓ	Average number of pores having a unit length [cm]
L	Avogadro number [6.0225×10^{23} molecules mol ⁻¹]
P	Swelling pressure [erg cm ⁻³]
P_w , P_a and $P_c = P_w - P_a$	Water, air and capillary pressures, respectively [erg cm ³]
r	Equivalent radius of water-filled pore [cm]
R	c_{Na}/c_{Ca} [dimensionless]
R_f	Retardation factor [dimensionless]
s	Position of the plane of the charged surface [cm]
SAR	Sodium adsorption ratio ($=C_{Na}/\sqrt{C_{Ca}/2}$) [(meql ⁻¹) ^{1/2}]
T	Absolute temperature [Kelvin degrees]
V	Volume [cm ³]
v_i	Sub-volume ($\sum v_i = V$) [cm ³]
x	Distance [cm]
Y	Scaled electrical potential [molecule electron ⁻¹]
Y_s	Value of Y at the charged surface [molecule electron ⁻¹]
Y_d	Value of Y at the mid-plane between two adjacent tactoids [molecule electron ⁻¹]
$Z_{(.)}$	Valence of the ion (.) [electron molecule ⁻¹]
α	$8000\pi/LDkT$ (Eq. 7) [erg mol ⁻¹]
β	Pore size distribution index [dimensionless]
γ	Specific gravity of water [g cm ⁻² s ⁻²]
Γ_s	Surface charge density [esu cm ⁻²]
Γ_{Cl}	Quantity of the excluded chloride per unit area of the charged surface [meq cm ⁻²]
Γ_{Na}	Quantity of sodium ionic charges per unit area of the charged surface [esu cm ⁻²]
δ	Space charge density [esu cm ⁻³]
ϵ	Electronic charge [4.803×10^{-10} esu electron ⁻¹]
η	Dynamic viscosity of water [g cm ⁻¹ s ⁻¹]
θ	Volumetric water content [cm ³ cm ⁻³]
θ_s , θ_r	Saturated and residual values of θ [cm ³ cm ⁻³]
Θ	Effective water saturation [dimensionless]
κ	Permeability [cm ²]
ρ_b	Bulk density [g cm ⁻³]
σ	Surface tension at the air-water interface [erg cm ⁻²]
v	Volume of water retained by clay particles in a unit volume of soil [cm ³ cm ⁻³]
φ	Porosity [cm ³ cm ⁻³]
ψ	Electrical potential [erg esu ⁻¹]

Introduction

Soil salinity arises from dissolved salts in soil solution, introduced by capillary rise and evaporation from deeper soil or from irrigation with water containing salts. A shortage of rain and water resources exists in semi-arid and arid zones, necessitating the use of low-quality water (LQW) such as saline water and treated sewage water (TSW) for irrigation, thereby preserving scarce fresh water resources to meet the increasing demand of the urban sector (e.g., [Hamilton et al., 2007](#) and [Qadir et al., 2007](#)). Inasmuch as LQW may contain relatively large quantities of soluble salts, its use for irrigation may accelerate the contamination or the salinization of soils and aquifers underneath the irrigated regions (e.g., [Assouline et al., 2015](#)).

Quantitative field-scale descriptions of chemical transport in the vadose (unsaturated) zone, therefore, are essential for improving the basic understanding of the transport of LQW in near-surface geological environments. They provide predictive tools, that, in turn, can be used to predict the future spread of LQW in these environments and to assess, reliably, the threat to soils and the underlying water supplies posed by using LQW irrigation.

Modelling irrigation with LQW, and, particularly, with TSW, requires at least three sub-systems to be taken into account in the effort: (i) the N-C-O sub-system describing the cycling of nitrogen and carbon compounds in the unsaturated zone; (ii) the major ions sub-system (Cl , SO_4 , HCO_3 , Ca , Mg , Na , and K) contributing to salinity; and (iii) phosphate, boron, and trace metals. The focus of this chapter is on the effect of soil salinity on the soil hydraulic properties, through soil solution-soil matrix (SS-SM) interactions. Consequently and for simplification, the practical soil-water system containing only the major ions in the irrigation water is considered here.

The SS-SM interactions include phenomena such as cation exchange, anion exclusion, precipitation and dissolution, swelling and reorganization of the soil colloid structures and, concurrently, rearrangement of the soil pore size distribution; the latter may affect the soil hydraulic conductivity and soil water retention (e.g., McNeal, 1968; Russo and Bresler, 1977a,b). These interactions, therefore, may affect water flow and solute transport markedly. The magnitude of the SS-SM interactions depends upon the types and amounts of inorganic and organic soil colloids. Among soil mineral colloids, the most reactive constituents are the smectite minerals (e.g., montmorillonite, beidellite, montronite), characterized by a dioctahedral structure. The presence of these minerals imparts a considerable cation exchange capacity or specific surface area to soils in arid and semi-arid regions. Furthermore, the smectite minerals are capable of considerable expansion at moderate to high exchangeable sodium levels in the presence of relatively low-salt soil solution concentrations. For comprehensive reviews, see Bresler et al. (1982) and Shainberg (1984). Hence, they can impart substantial salinity-dependent soil water retention and soil hydraulic conductivity changes, and, concurrently, may considerably affect water flow and solute transport (e.g., Russo, 1988, 2010, 2013).

The present chapter concentrates on the effect of salinity on soil physical properties relevant to flow and transport, in particular soil water retention and hydraulic conductivity. Experimental evidence on the effect of soil salinity on soil water retention and hydraulic conductivity, together with an approach to model these entities in salt-affected soils are presented and discussed. Implications of the results of these analyses for flow and transport in salt-affected soils are demonstrated and assessed.

Water retention and swelling in salt-affected soils

The amount of water retained by soil depends largely upon the soil's mineral and organic colloid contents, although the structural arrangement of soil pores may also be of considerable importance. In particular, the presence of substantial quantities of soil organic matter or smectite minerals results in a considerable water retention capacity. Soils with high smectite content may also swell considerably more in the presence of high sodium or high salt concentrations. Soils high in organic colloids are much more stable and do not tend to swell excessively under adverse chemical conditions. They may disperse, however, at high pH levels or in the presence of low salt concentrations (Bresler et al., 1982).

Following Russo and Bresler (1977a), the effects of concentration and composition of the soil solution on the water retention on the local (Darcy) scale, in a soil containing 20% clay (dominated by montmorillonite) are depicted in Fig. 1, for a simple but practical soil water system containing Cl , Na and Ca ions only.

The functional relationships (under wetting conditions) in Fig. 1 are given in terms of the capillary pressure head, h , (considered here as a positive quantity), volumetric soil-water content, θ , and equilibrium solution concentration, $C = C_{\text{Na}} + C_{\text{Ca}}$, where C is concentration in meq/l , and composition (expressed in terms of sodium adsorption ratio, $\text{SAR} = C_{\text{Na}}/\sqrt{(C_{\text{Ca}}/2)}$). The points in Fig. 1 represent actual measurements for various values of SAR and C . The solid lines represent best visual fits between measured points. Note that the ordinate scale of Fig. 1 is a shift upward by one order of magnitude, and the data accordingly translated along this axis, to distinguish between different sets of concentrations. In general, each of the water retention relationships in Fig. 1 can be represented by a single continuous curve. When solution concentration exceeds 50 meq/l , a single-valued function is obtained for any value of SAR. The same is true for $\text{SAR} = 0$ and $2 \text{ meq/l} \leq C \leq 5 \text{ meq/l}$, as can be seen from the lowest curve of Fig. 1. Within the range $2 \text{ meq/l} \leq C \leq 10 \text{ meq/l}$ and $0 \leq \text{SAR} \leq 50$, water content, θ depends not only on h , but also on both concentration and composition of the soil solution. For a given h , θ increases as C decreases and SAR increases.

The experimental findings presented in Fig. 1 can be qualitatively explained in terms of electrostatic properties and the porous nature of the soil. It is assumed that the soil pore space can be divided into structural and textural porosity. The latter is regarded as an intrinsic property of the soil, arising from the size and arrangement of basic particles within the soil mass. In these pores the $h(\theta)$ function can be determined quantitatively from the pressure that develops between the clay platelets, within the clay mass between the pores as the soil solution composition and concentration vary.

The classical view of the osmotic pressure of soil colloids is that cations in the diffuse layer between clay particles reduce the free energy of the water relative to that in the external equilibrium solution. This causes water molecules to diffuse into the space between the clay particles, since the cations are electro-statically constrained from leaving the interlayer region. Hence, the particles move apart to accommodate the extra water. If, on the other hand, the clay particles are confined, hydraulic pressure develops between them. For a Na/Ca-Cl soil-water system, this pressure may be determined, based on the mixed-ion diffuse double-layer theory (Bresler, 1972), see Eq. (2) below.

Fig. 1 Capillary pressure head, h , as a function of water content, θ , for selected values of the concentration, C , and the sodium adsorption ratio, SAR, of the equilibrium solution. Arrows indicate that the point $h = 10$ cm is shifted and the data are translated along the h -axis. Reproduced from Russo D and Bresler E (1977a) Effect of mixed Na-Ca solutions on the hydraulic properties of unsaturated soils. *Soil Science Society of America Journal* 41: 714–717.

Eq. (2) provides a reasonably good first-order approximation of the water retention forces acting within the textural porosity. It predicts that for a given hydrostatic pressure, P , the volume of water retained by the clay mass (which is proportional to the distance between the clay particles) increases as the equilibrium solution becomes more diluted (C decreases) and less dominated by the divalent ion (SAR increases). In the structural pores, which are sensitive to external forces arising from interactions between clay particles within the textural porosity, the $h(\theta)$ function can be determined from the pressure within the water-filled pores relative to that within the air-filled pores. In the former pores, at equilibrium, the pressure increases as the pore radius decreases, or for a given pressure, higher values of θ are associated with a larger number of pores having a given corresponding radius. Thus, the functional relationships between h and θ in the structural porosity depend on the total porosity and the pore size distribution. For a given pressure, the space between the clay particles increases as SAR increases and as C decreases. This leads to an increasing amount of water retained by the clay mass, and concurrently to the swelling of the clay mass so that it occupies a larger volume. For a constant-volume system, changes in the volume of the clay mass are at the expense of the structural porosity and its pore size distribution. Thus, as can be observed in Fig. 1, for a given capillary pressure head, the amount of water retained by the soil increases with decreasing C and increasing SAR.

Soil hydraulic conductivity in salt-affected soils

The retention curves in Fig. 1 represent the soil's pore size distribution to some extent. The data in Fig. 1, therefore, suggests that swelling of the clay fraction within the soil, induced by relatively low C and high SAR, may alter the geometry of the soil pores and thus affect the intrinsic soil permeability, $\kappa(\theta)$. Investigations (e.g., McNeal, 1968) have confirmed that soil permeability or hydraulic conductivity, $K(\theta) = \kappa(\theta)\gamma/\eta$, where γ and η are the specific gravity and the dynamic viscosity of water, respectively, is highly affected by the soil solution concentration, C , and composition, expressed in terms of SAR. It has been suggested that the swelling of clay particles in a confined soil system causes the size of large soil pores to decrease, and that breakdown of domains of clay platelets (tactoids) (Blackmore and Miller, 1961; Shainberg and Kaiserman, 1969) and the subsequent movement and dispersion of the clay platelets may further block soil pores. Low permeability can result from such geometric restrictions. Investigators found a positive correlation between relative soil permeability and the swelling of extracted soil clays, which, in turn, was affected by the soil solution concentration and composition. Inasmuch as soil solution composition may affect the breakdown of tactoids (and the subsequent movement and dispersion of clay platelets) on the one hand, and soil swelling on the

other hand, in much the same way, the relative importance of swelling and dispersion in affecting soil permeability remains essentially unresolved (Shainberg and Kaiserman, 1969). There are situations (e.g., relatively coarse-textured soils associated with relatively high influx rates), in which the de-mixing of adsorbed ions, which concentrates Na on external particle surfaces, may lead to the breakdown of tactoids and the subsequent movement and dispersion of clay platelets.

Following Russo and Bresler (1977a), the effect of concentration and composition of the soil solution on the soil hydraulic conductivity function $K(\theta)$ at the local (Darcy) scale, for the same soil as in Fig. 1, is depicted in Fig. 2.

The functional relationships presented in Fig. 2 are given in terms of water content, θ , and equilibrium solution concentration, C and composition, SAR. The points in Fig. 2 represent actual measurements for various values of SAR and C . The solid lines represent best visual fits between measured points. Note that the abscissa scale in Fig. 2 has been shifted to the right and the data are accordingly translated along the θ -axis to distinguish among different sets of concentrations.

In general, each of the $K(\theta)$ functions in Fig. 2 can be represented by a single continuous curve. Furthermore, for the calcium-saturated system ($SAR = 0$ and $2 \text{ meq/l} \leq C \leq 50 \text{ meq/l}$), a single-valued $K(\theta)$ is obtained. In the mixed Na-Ca system, however, values of $K(\theta)$ decrease with both θ and C for a given SAR. The differences among the various functions increase as θ becomes larger and as C becomes smaller. These differences are pronounced when SAR and θ are greater than 15 and 0.25, respectively, and when C is equal to or less than 10 meq/l . In other words, relatively low values of soil water content compensate for the negative effects of high SAR and low C on the hydraulic conductivity.

The experimental data depicted in Fig. 2 can be explained qualitatively in terms of soil-water-clay interactions and the porous nature of the soil. The unsaturated hydraulic conductivity function, $K(\theta)$, depends upon the size distribution of water-filled pores and the total water-filled porosity. As mentioned in the previous section, the diffuse double-layer theory for mixed-electrolyte systems predicts that for a given pressure, the space between clay particles, and, concurrently, the amount of water retained by the clay mass, increases as SAR increases and as C decreases. For a constant-volume system, changes in the volume of the clay mass are at the expense of the quantity and distribution of the soil pores. Thus, for a given h , the amount of water retained by the soil increases (Fig. 1) and the hydraulic conductivity decreases (Fig. 2) as SAR becomes larger and solution concentration, C decreases. Since the swelling of clay decreases as h increases, the increase in the water volume retained and the decrease in hydraulic conductivity become smaller as h increases. In addition, both water content and hydraulic conductivity, and concurrently water velocity, may considerably decrease with increasing h . Consequently, increasing h may reduce the possibility that movement and dispersion of clay platelets will lead to additional blocking of the pore space available for water flow.

Fig. 2 Hydraulic conductivity, K , as a function of water content, θ , for selected values of the concentration, C , and the sodium adsorption ratio, SAR, of the equilibrium solution. Arrows indicate that the point $\theta = 0$ is shifted and the data are translated along the θ -axis. Reproduced from Russo D and Bresler E (1977a) Effect of mixed Na-Ca solutions on the hydraulic properties of unsaturated soils. *Soil Science Society of America Journal* 41: 714–717.

Modelling hydraulic conductivity and water retention in salt-affected soils

In the preceding sections it was shown that in salt-affected soils, both the local-scale soil hydraulic conductivity, $K(h)$, and the soil water retention, $\theta(h)$, may depend on soil solution concentration and composition. Ion precipitation or dissolution will have impacts, but following Russo and Bresler (1977b) and Russo (1988), a simple but credible soil-water system can contain just Na, Ca and Cl ions. The equilibrium solution is quantified in terms of the sum of the molar concentrations of the cations, $C_0 = c_{Na} + c_{Ca}$, and the ratio between the molar concentration of mono- and di-valent cations, $R = c_{Na}/c_{Ca}$.

For the modelling of the soil hydraulic conductivity, $K(h, R, C_0)$, and the soil water retention, $\theta(h, R, C_0)$, functions at the local (Darcy) scale, processes and entities relevant to the micro (pore) scale should be taken into account. It is assumed that: (i) the soil clay fraction is mostly montmorillonite (having a constant effective surface charge density, Γ_s), which may exist in packets of platelets or domains (tactoids); (ii) the ions on the external surfaces of the tactoids (the "exchange phase") are distributed according to the planar mixed-ion diffuse double-layer theory; (iii) the number of clay platelets per tactoid depends on the pressure acting on the soil-water system, and on the exchangeable sodium percentage, ESP; and (iv) due to the continuity of the pressure in the soil solution, the pressure difference between two adjacent clay particles and the bulk solution (given by the swelling pressure, P (Eq. (2) below) is equal to the pressure difference across the air-water interface within the soil pores. In other words, the difference between the pore water pressure, P_w , and the atmospheric pressure, P_a , as given by the capillary pressure, $P_c = P_w - P_a = -\gamma h$.

Calculations of the $b(h, R, C_0)$ and the $N(h, R, C_0)$ functions

For the Na/Ca-Cl soil-system considered here, the general equation of the interacting double layer is obtained from the first integration of the one-dimensional Poisson-Boltzmann equation given by:

$$\frac{dY}{dx} = \frac{G}{\sqrt{R+1}} [R(e^{Z_{Na}Y} - e^{Z_{Na}Y_d}) + (e^{Z_{Ca}Y} - e^{Z_{Ca}Y_d}) + (R+2)(e^{Z_{Cl}Y} - e^{Z_{Cl}Y_d})]^{1/2} \quad (1)$$

where $Y = e\psi/kT$ is the scaled electrical potential, $Z_{()}$ is the valence of the ion ($\cdot$); ψ is the electrical potential; e is the charge on the electron; k is Boltzmann's constant; T is the absolute temperature; x is the distance to the charged surface (where $x = s$ and $Y = Y_s$); Y_d is Y at the midplane between two adjacent tactoids (at the plane $x = d$, where $dY/dx = 0$), $G = (8\pi C_0 L e^2 / 10^3 D k T)^{1/2}$; L is Avogadro's number, and D is the dielectric constant of the bulk solution.

For dilute solutions, the swelling pressure, P , i.e., the pressure difference between the equilibrium solution (where $Y = 0$) and the mid-plane between two adjacent tactoids (at the plane $x = d$, where $Y = Y_d$), is obtained by substituting the Boltzmann distribution law into the Van't Hoff relation. For the Na/Ca-Cl soil system considered here, with tactoids which are at a distance of $2b$ apart (where $b = d - s$), the swelling pressure, P , is given by:

$$P = B [R(e^{Z_{Na}Y_d} - 1) + (e^{Z_{Ca}Y_d} - 1) + (R+2)(e^{Z_{Cl}Y_d} - 1)] \quad (2)$$

where $B = kLTC_0/10^3(R+1)$. Substituting $P = \gamma h$ in (2), one can obtain after rearrangement

$$a_1 e^{Z_{Na}Y_d} + a_2 e^{Z_{Ca}Y_d} + a_3 e^{Z_{Cl}Y_d} + a_4 = 0 \quad (3)$$

Thus, the solution of the nonlinear equation (3) yields Y_d as a function of h , R , and C_0 . Estimation of $b(h, R, C_0)$ also requires the knowledge of the scaled electrical potential at the charged surface, Y_s , which can be estimated from the integration of Eq. (1) and from the condition of electro-neutrality requiring that the surface charge density, Γ_s , be equal to the total space charge density, $\delta(x)$, within the range $s \leq x \leq d$, thus

$$\left(\frac{dY}{dx}\right)_{x=s} = \frac{4\pi e \Gamma_s}{DkT} \quad (4)$$

Evaluating (1) at the plane $x = s$ (where $Y = Y_s$), using (4), one obtains after rearrangement

$$a_1 e^{Z_{Na}Y_s} + a_2 e^{Z_{Ca}Y_s} + a_3 e^{Z_{Cl}Y_s} + a_4 = 0 \quad (5)$$

where $a_4 = -\{2\pi 10^3(R+1)\Gamma_s^2/LDkTC_0\} + a_1 e^{Z_{Na}Y_d} + a_2 e^{Z_{Ca}Y_d} + a_3 e^{Z_{Cl}Y_d}$, and a_i , $i = 1, 2, 3$ as before.

The solution of the nonlinear equation (5) yields Y_s as a function of Γ_s , R , C_0 , and $Y_d(h, R, C_0)$. From the values of Y_d and Y_s , the distance from the midplane $x = d$ (where $dY/dx = 0$ and $Y = Y_d$) to the charged surface (where $x = s$ and $Y = Y_s$), $b = d - s$, is obtained by direct integration of (1). Rearranging (1) yields

$$\frac{G}{\sqrt{R+1}} \int_d^s dx = \int_{Y_d}^{Y_s} (a_1 e^{Z_{Na}Y} + a_2 e^{Z_{Ca}Y} + a_3 e^{Z_{Cl}Y} + a_4)^{-1/2} dY \quad (6)$$

where $a_4 = -[a_1 e^{Z_{Na}Y_d} + a_2 e^{Z_{Ca}Y_d} + a_3 e^{Z_{Cl}Y_d}]$ and a_i , $i = 1, 2, 3$ as before. Thus, a numerical integration of (6) yields $b = d - s$ as a function of h , R , and C_0 .

Once $Y_d(h, R, C_0)$ has been estimated from Eq. (3), the fractional excess of Na on the exchange phase, Γ_{Na}/Γ_s is estimated from

$$\frac{\Gamma_{Na}}{\Gamma_s} = \frac{R\sqrt{C_0}}{\Gamma_s\sqrt{\alpha(R+1)}} \sinh^{-1} \left(\frac{\Gamma_s}{\sqrt{C_0}} \frac{\sqrt{\alpha(R+1)}}{(R+4 \cosh Y_d)} \right) \quad (7)$$

where Γ_{Na} is the quantity of sodium ionic charges per unit area of the charged surface, and $\alpha = 8000\pi/L\epsilon\kappa T$. Note that, inasmuch as $Y_d = Y_d(h, R, C_0)$, the exchangeable sodium percentage, $ESP = 100\Gamma_{Na}/\Gamma_s$ is also a function of h , R and C_0 . For given pressure head, h and $ESP(h, R, C_0)$, the number of clay platelets per tactoid, $N = N[h, ESP(h, R, C_0)]$ is calculated by using experimental data on the dependence of N on h in a calcium system, and by experimental data on the dependence of N on ESP in clay suspensions (Shainberg and Kaiserman, 1969).

Calculations of the $\theta(h, R, C_0)$ and the $K(h, R, C_0)$ functions

Following Russo and Bresler (1977b) and Russo (1988), to estimate the $K(h, R, C_0)$ and the $\theta(h, R, C_0)$ functions at the local scale, a confined volume element, V , of a homogeneous and isotropic porous medium with uniform porosity, ϕ^0 , is considered. This soil volume, which is large compared with the typical pore size of the porous medium, is subdivided into n equal sub-volumes, v_i , $i = 1$ to n . Each sub-volume, v_i , is associated with single values of the average pressure head, h_i , the equivalent radius of the water-filled pores, $r_i^0 = 2\sigma/\gamma h_i$, (with σ being the surface tension at the air-water interface), and the average number of pores having a unit length, $\ell_i = \phi^0 v_i / \pi (r_i^0)^2$. Making use of the functions $b(h_i, R, C_0)$ and $N(h_i, R, C_0)$, the water content, θ_i , in each v_i is calculated from:

$$\theta_i(h_i, R, C_0) = \theta_i^0(h_i) + [v_i(h_i, R, C_0) - v_i^0(h_i)] \quad (8)$$

where θ_i^0 is the water content in a reference state (that is, a soil in equilibrium with a concentrated calcium chloride solution), at pressure head, h_i . v_i^0 and v_i are the volumes of water retained by the clay particles in a unit volume of the soil, in the reference state, and in equilibrium with a soil solution of a given R and C_0 , given by:

$$v_i^0(h_i) = \frac{A_s}{2N_i^0(h_i)} \{ 2b_i^0(h_i) + 2b_0 [N_i^0(h_i) - 1] \} \rho_b \quad (9)$$

$$v_i(h_i, R, C_0) = \frac{A_s}{2N_i^0(h_i)} \{ 2b_i(h_i, R, C_0) [1 + N_i^0(h_i) - N_i(h_i, R, C_0)] + 2b_0 [N_i(h_i, R, C_0) - 1] \} \rho_b \quad (10)$$

respectively, where A_s and ρ_b are the specific surface area and the bulk density, respectively, of the soil at the reference state, the superscript zero refers to the reference state, and $2b_0$ is the thickness of the water film between two adjacent clay platelets within a tactoid ($2b_0 = 9 \times 10^{-8}$ cm, regardless of h , R , or C_0). Similarly, since in the confined soil element the increment in the water retained by the clay fraction is at the expense of the pore space in which water flow takes place, the effective porosity, ϕ_i , in each sub-volume, v_i , is given by

$$\phi_i(h_i, R, C_0) = \theta_i^0(h_i) - [v_i(h_i, R, C_0) - v_i^0(h_i)] \quad (11)$$

and the mean equivalent radius of the pores, r_i , in each sub-volume, v_i is given by

$$r_i(h_i, R, C_0) = \left[\frac{\phi_i(h_i, R, C_0) v_i}{\pi \ell_i} \right]^{1/2} \quad (12)$$

Given the values of $\phi_i(h_i, R, C_0)$ and $r_i(h_i, R, C_0)$, the relative hydraulic conductivity is calculated on the basis of the capillary bundle theory (e.g., Childs and Collis-George, 1950; Brutsaert, 1967). Using a modified Series-Parallel model of the porous medium, the hydraulic conductivity relative to the reference state, is given (Marshall, 1958) by

$$K_i^r(h_i, R, C_0) = \frac{[\phi_i(h_i, R, C_0)]^2 \sum_{j=1}^n [2j-1] [r_j(h_j, R, C_0)]^2}{[\phi_i^0(h_i)]^2 \sum_{j=1}^n [2j-1] [r_j^0(h_j)]^2} \quad (13)$$

where ϕ_i^0 is the soil effective porosity in sub-volume, v_i , in the "stable" reference state, $h_i < h_{i+1}$, and $i = 1$ to n . Thus, the soil hydraulic conductivity, K_i , given by

$$K_i(h_i, R, C_0) = K_i^0(h_i) K_i^r(h_i, R, C_0) \quad (14)$$

where $K^0(h)$ is the hydraulic conductivity function of the soil at the "stable" reference state.

Following Russo and Bresler (1977b), a comparison between the calculated and measured water retention curves in the soil presented in the previous figures, for different combinations of $C = 10^{-3} C_0 [1 + (R+1)^{-1}]$ and $SAR = R[10^3 C_0 (R+1)^{-1}]^{1/2}$, is depicted in Fig. 3.

Fig. 3 Capillary pressure head, h , as a function of water content, θ , for selected values of the concentration, C , and the sodium adsorption ratio, SAR, of the equilibrium solution. Computed results (solid lines) are compared with measured data (dashed lines). Arrows indicate that the point $\theta = 0.10$ is shifted and the data are translated along the θ -axis. Reproduced from Russo (1976) *M.Sc. thesis (in Hebrew)*, Faculty of Agriculture in Rehovot, The Hebrew University, Jerusalem.

The abscissa scale in Fig. 3 is shifted to the right, and the data are accordingly translated along the θ axis to distinguish between the calculated and the measured curves for different sets of concentrations. For calcium-saturated soil ($SAR = 0$), the experimental retention curves are independent of the solution concentration, whereas the calculated curves are slightly dependent on it. The small discrepancy between the calculated and the measured curves can serve as a measure of the error in the assumptions and of the ability of the calculations to predict soil-water retention. For the mixed systems, there is reasonably good agreement between measured and calculated retention curves. The agreement improves for lower sodic systems (SAR decreases) and as the system becomes more concentrated (C increases).

A comparison between calculated and measured relative hydraulic conductivity, $K^r = K(\Theta, SAR, C)/K^0(\Theta)$, where $\Theta = (\theta - \theta_r)/(\theta_s - \theta_r)$ is the effective water saturation, and θ_s and θ_r are the saturated and residual values of θ , respectively, for the same soil as in the previous figures, for various combinations of Θ , C and SAR , is presented in Fig. 4.

The abscissa scale in Fig. 4 is shifted to the right and the data accordingly translated along the SAR axis to distinguish between the calculated and the measured curves for different sets of concentrations. It can be seen (Fig. 4) that there is relatively good agreement between calculated and measured data in most cases. For the combinations of Θ , SAR and C depicted in Fig. 4, the calculated K^r deviates by less than twice the value of the measured K^r .

The comparison between calculated and experimental results indicates that a reasonable first-order approximation to the soil-water retention and soil hydraulic conductivity functions can be obtained for relatively wide ranges of soil-solution concentrations and compositions. This can be achieved by taking into account the porous nature of the soil, the interactions between the charged solid phase and the ions in the liquid phase within the soil, and the effects of the water pressure and the soil solution composition on the organization and structure of the clay platelets.

Fig. 4 Relative hydraulic conductivity, K_r , as a function of the sodium adsorption ratio, SAR, of the equilibrium solution, for selected values of the solution concentration, C , and degree of water saturation, Θ . Computed results (solid lines) are compared with measured data (dashed lines). Arrows indicate that the point $SAR = 0$ is shifted and the data are translated along the SAR-axis. Reproduced from Russo D and Bresler E (1977b) Analysis of the saturated-unsaturated hydraulic conductivity in a mixed Na-Ca soil system. *Soil Science Society of America Journal* 41: 706–710.

Soils of differing textures, containing clay fractions that are mostly montmorillonite, have essentially the same surface charge density ($\Gamma_s \approx 4.5 \times 10^4$ esu/cm²); consequently, they are characterized by essentially the same $\Gamma_{Na}(h, R, C_0)/\Gamma_s$ (Eq. 7) and $\Gamma_{Cl}(h, R, C_0)$ (see Eq. (16) below) relationships. On the other hand, the $\theta(h, R, C_0)$ and the $K^f(h, R, C_0)$ functions (Fig. 5), and, concurrently, the $K(h, R, C_0) = K^0(h)K^f(h, R, C_0)$ functions, associated with soils of different texture (see Table 1) may be quite different (Russo, 1988).

The functions depicted in Fig. 5 suggest that the SS-SM interactions affect the differences among the various soil types, with respect to their hydraulic properties. In the case of the water retention curves, the differences between the values of θ associated with the various soils generally increase as h and SAR increase and as C decreases. As for the hydraulic conductivity function, the differences between the values of K^f , and concurrently, between values of $K = K^f K^0$, associated with the various soils increase as SAR increases and as h and C decrease. Fig. 5 suggests that because of SS-SM interactions, the capability of the coarse-textured soil to transmit water and solutes faster than the finer-textured soils is extended to a larger pressure head (smaller degree of saturation) as the soil solution SAR increases and as C decreases.

Both the experimental and the theoretical results presented in the previous sections suggest that for a given soil solution concentration and composition, the effect of the SS-SM interactions on the hydraulic conductivity decreases with decreasing water saturation. Following Russo (1988), this is demonstrated in Fig. 6, in which combinations of soil solution concentration (C) and composition (SAR) required to maintain $K^f \geq 0.75$ (that is, no more than a 25% reduction in K relative to the “stable” reference state), are given for various degrees of water saturation, and for soils of different textures (Table 1). Note that the curves in Fig. 6 generalize the concept of the “threshold concentration” in terms of soil properties and soil water status. Consequently, they may be used for water quality classification in relation to soils of different textures, and for irrigation management. For a given SAR , the solution concentration required to maintain $K^f \geq 0.75$ (that is, the “threshold concentration”) decreases as the soil water content decreases and as the soil’s texture becomes coarser. Fig. 6 suggests that a decrease in the water application rate, and, concurrently, in soil water saturation, may improve the efficiency of the reclamation of sodic soils, especially, fine-textured ones.

General implications for flow and transport

Generally, for a given soil and given boundary and initial conditions, water flow is governed by the soil hydraulic properties. Thus, the effect of the SS-SM interactions is to reduce the water flow relative to that of a “stable” reference soil. For a given soil, the retardation of the water movement by the SS-SM interactions, will increase as either the initial soil solution SAR or the SAR of the applied water increases, as either the initial soil solution concentration or the solution concentration of the applied water decreases, and as the surface water application rate increases.

Solute transport, in turn, is governed by water flow and by cation exchange and anion exclusion. In the case of transport, therefore, the SS-SM interactions may act in two opposing directions: the retardation of the solute movement because of reductions in the soil hydraulic conductivity and because of cation exchange, and the acceleration of the solute movement because of anion exclusion. The retardation effect caused by the reductions in the soil hydraulic conductivity, and, concurrently, in water velocity, increases with increasing SAR and decreasing C and h , especially in relatively fine-textured soils. The retardation effect because of Na/Ca exchange is given by the retardation factor, R_f

Fig. 5 Relative hydraulic conductivity, K_r , (a) and water content, θ , (b) as a function of the capillary pressure head, h for selected values of the concentration, C , and the sodium adsorption ratio, SAR, of the equilibrium solution, for three soils of different texture, loamy sand (LS), loam (L), and clay loam (CL). Table 1 Representative values for relevant soil physical properties.

Soil texture	Clay fraction	A_s cm ² /g	CEC meq/g	K_s cm/h	h_b cm	B	θ_s cm ³ /cm ³	θ_r cm ³ /cm ³	ρ_b g/cm ³
Loamy sand	0.06	3.6×10^5	0.056	5.56	9.1	0.30	0.410	0.015	1.53
Loam	0.19	9.5×10^5	0.145	2.50	48.0	0.23	0.451	0.042	1.43
Clay Loam	0.34	1.7×10^6	0.248	0.77	63.4	0.15	0.476	0.068	1.33

A_s , CEC and ρ_b are the soil specific surface area, cation exchange capacity and bulk density, respectively;

K_s , θ_s and θ_r are the soil saturated hydraulic conductivity, and saturated and residual water contents, respectively;

h_b and β are the soil bubbling pressure head and pore size distribution index, respectively.

Reproduced from Russo D (1988) Numerical analysis of the non-steady transport of interacting solutes through unsaturated soil. 1. Homogeneous systems. *Water Resources Research* 24: 271–284.

$$R_f(h, R, C_0) = 1 + \frac{[R + 1] \Gamma_{Na}(h, R, C_0) F A_{ad} \rho_b}{Z_{Na} R C_0 \theta(h)} \quad (15)$$

where F is the Faraday constant, A_{ad} is the specific adsorption surface area of the soil, and Γ_{Na} is the quantity of sodium ionic charges per unit area of the charged surface (Eq. 7). The retardation caused by Na/Ca exchange (expressed in terms of R_f) increases with increasing SAR and decreasing C and h , especially in relatively fine-textured soils.

Anion exclusion can be calculated from the distribution of the scaled electrical potential, $Y(x)$ (Eq. 1) within the domain $s \leq x \leq d$, which, in turn, for given values of $b(h, R, C_0)$ and $Y_s(h, R, C_0)$, is obtained from the solution of Eq. (1), using the Runge-Kutta method. Applying the Boltzmann distribution law for the Na/Ca-Cl system considered here, the amount of excluded chloride per unit surface area, is calculated from

Fig. 6 Combinations of the concentration, C , and the sodium adsorption ratio, SAR, of the equilibrium solution, and degree of water saturation, Θ (the numbers labeling the curves) at which 25% reduction in hydraulic conductivity occurs, for three soils of different texture, loamy sand (LS), loam (L), and clay loam (CL). Reproduced from Russo D (1988) Numerical analysis of the non-steady transport of interacting solutes through unsaturated soil. 1. Homogeneous systems. *Water Resources Research* 24: 271–284.

$$\Gamma_{Cl}(h, R, C_0) = \frac{|Z_{Cl}| C_0 (R + 2)}{(R + 1)} \cdot \int_s^d \{1 - \exp[-Y(x; h, R, C_0)]\} dx \quad (16)$$

which, in turn, is used to calculate the elution factor, E_f , given by

$$E_f(h, R, C_0) = 1 - \frac{[R + 1] \Gamma_{Cl}(h, R, C_0) A_{ex} \rho_b}{|Z_{Cl}| C_0 [R + 2] \theta(h)} \quad (17)$$

where A_{ex} is the specific exclusion surface area.

The acceleration effect due to the chloride exclusion, which is determined by the second term on the right-hand side of Eq. (17), increases with increasing SAR and decreasing C and h , especially in relatively fine-textured soils. The net effect of the SS-SM interactions on the solute transport is determined, therefore, by the relative magnitudes of all of these processes, which, in turn, depend on the soil type and the boundary and initial conditions imposed on the flow system.

Flow and transport in a realistic salt-affected soil

The coupling-interaction parameters on the field scale

For given soil, crop, or weather, or quantity and quality of the irrigation water, solute transport couples with water flow because of its dependence on the Darcy velocities. In the case of irrigation with interacting mixed Na/Ca salts, water flow itself is coupled to the transport through the dependence of the hydraulic properties on solute concentrations. In this case, the relevant soil properties (referred to hereafter as the coupling-interaction parameters, CIPs), include the soil hydraulic conductivity, K , the soil water content,

θ , the retardation factors for Na and Ca, R_f^{Na} and R_f^{Ca} , respectively, and the elution factor for Cl, E_f , all as functions of the pressure head and the composition of the soil solution.

The theoretical framework described earlier in this chapter evaluates the CIPs on the macroscopic (Darcy) scale, pertinent to flow and transport processes at laboratory scale. Evaluation of the CIPs on a larger scale, more amenable to flow and transport processes in realistic, field-scale, spatially heterogeneous soils, requires coupling of the theoretical approach with measured spatial distributions of the relevant soil properties. The latter include the hydraulic conductivity and the water retention functions at an inert reference state, the soil cation exchange capacity, CEC, the soil specific surface area, A_s , and the soil bulk density, ρ_b . Following Russo (2013), the resultant spatial distributions of the CIPs, in turn, are quantified in terms of their probability density functions (PDFs), expressed as functions of the soil solution concentration and composition and the pressure head (Fig. 7).

The equations governing flow and transport of interacting solutes in spatially heterogeneous, variably saturated soils

It is assumed here that water flow is described locally by the 3-D Richardson-Richards equation, the physical parameters of which are viewed as realizations of 3-D, second-order, stationary random space functions, characterized completely by a constant mean and a two-point, spatial covariance. It is further assumed that the transport of each of the ions of the mixed Na/Ca salt is described locally by the classical, one-region, 3-D advection-dispersion equation (ADE). When the ions in the soil solution interact with the soil matrix, the properties of the spatially heterogeneous soil that affect flow and transport are expressed as functions of the spatial coordinate vector, $\underline{x}$, and flow-controlled attributes. The latter include the pressure head, ψ , the sum of the molar concentration of the cations, $C_0 = c_{\text{Na}} + c_{\text{Ca}}$ [mol ℓ^{-1}], and the ratio between the molar concentration of the mono- and the divalent cations, $R = c_{\text{Na}}/c_{\text{Ca}}$, in the soil solution.

In a Cartesian coordinate system (x_1, x_2, x_3), where x_1 is directed vertically downwards, assuming local isotropy, considering water uptake by the plant roots and neglecting local anisotropy and the effect of osmotic gradients on the flow, the Richardson-Richards equation governing flow in a non-rigid, 3-D variably saturated, spatially heterogeneous soil (Russo et al., 2004) is:

$$\frac{\partial(\theta^r \theta)}{\partial t} = \sum_{i=1}^3 \frac{\partial}{\partial x_i} \left[K^r K \frac{\partial \psi}{\partial x_i} \right] - \frac{\partial K^r K}{\partial x_1} - S_w \quad (18)$$

where t is time; $\psi = \psi(\underline{x}, t)$ is the pressure head; $\theta = \theta(\psi, \underline{x})$ and the scalar $K = K(\psi, \underline{x})$, are the volumetric water content and the hydraulic conductivity, respectively, of the soil in a rigid “stable” reference state, in which the changes in the soil PSD due to SS-SM interactions are negligibly small (i.e., when $R \rightarrow 0$, and $C_0 \rightarrow \infty$); $\theta^r = \theta^r(C_0, R, \psi, \underline{x})$ and $K^r = K^r(C_0, R, \psi, \underline{x})$ are relative water content, and relative hydraulic conductivity, respectively, resulting from the effect of the SS-SM interactions on the soil PSD, and $S_w = S_w(\underline{x}, t)$ is a sink term representing water uptake by the plant’s roots.

Similarly, assuming that the entire water-filled pore space is mobile, neglecting ion precipitation or dissolution, and neglecting ion uptake by the plant’s roots, the ADE governing transport of the mixed Na/Ca salt (Russo et al., 2004) is:

$$\frac{\partial(\theta_m^* c_m)}{\partial t} = \sum_{i=1}^3 \sum_{j=1}^3 \frac{\partial}{\partial x_i} \left\{ \theta D_{ij} \frac{\partial c_m}{\partial x_j} \right\} - \sum_{i=1}^3 \frac{\partial(u_i \theta c_m)}{\partial x_i} \quad (19)$$

where $m = 1$ to 3 indicates the chloride, sodium and calcium ions, respectively; c_m [mol ℓ^{-1}] is the resident solute concentration of the m -th ion, expressed as mass per unit volume of soil solution; θ_m^* is the “effective” volumetric water content, given by $\theta_m^* = \theta + \theta_{\text{exm}}$ and $\theta_m^* = \theta + \theta_{\text{adm}}$, for $m = 1$ and $m = 2, 3$, respectively, where $\theta_{\text{exm}}(\psi, \underline{x}, R, C_0, c_m)$ ($m = 1$) and $\theta_{\text{adm}}(\psi, \underline{x}, R, C_0, c_m)$ ($m = 2, 3$) are the exclusion and the adsorption volume fractions, respectively, calculated from the planar, mixed-ion diffuse-

Fig. 7 Cumulative distribution function of relative hydraulic conductivity, K_r , for different chloride concentrations (denoted by the numbers labeling the curves, in $\text{meq} \ell^{-1}$). Reproduced from Russo D (2013) Consequences of salinity-induced-time-dependent soil hydraulic properties on flow and transport in salt-affected soils. *Procedia Environmental Sciences* 19: 623–632, <https://doi.org/10.1016/j.proenv.2013.06.071>.

double-layer theory; u_i ($i = 1, 2, 3$) are the components of the Eulerian water velocity vector, and D_{ij} ($i, j = 1, 2, 3$) are the components of the pore-scale dispersion tensor. When molecular diffusion is small enough to be excluded from the analysis, D_{ij} given (Bear, 1972) as:

$$D_{ij} = \lambda_T |\underline{u}| \delta_{ij} + (\lambda_L - \lambda_T) u_i u_j / |\underline{u}| \quad (20)$$

where λ_L and λ_T are the longitudinal and the transverse components of the pore-scale dispersivity tensor; δ_{ij} is the Kronecker delta, and $|\underline{u}| = (u_1^2 + u_2^2 + u_3^2)^{1/2}$.

Details of the numerical methods used to solve the governing equations (18, 19), subject to the appropriate boundary and initial conditions are described elsewhere (Russo et al., 2004). The “mixed” form of Richardson-Richards equation governing flow in a three-dimensional domain (Eq. 18) is approximated by a fully implicit Euler scheme with a truncation error of $O(\Delta t, \Delta x_1^2, \Delta x_2^2, \Delta x_3^2)$. This scheme is convergent and unconditionally stable for the linear diffusion equation and has been found appropriate for flow problems in highly heterogeneous porous media, in which both steep gradients and saturated regions can develop.

The resulting system of nonlinear algebraic equations with respect to the pressure head, ψ , is solved iteratively, by applying the so-called modified Picard method. Picard (external) iterations are applied for both capillary and gravity terms and the resulting system of linear algebraic equations is solved by the polynomial preconditioned conjugate gradient (PPCG) method. The hydraulic conductivity between the numerical cells, the so-called inter-block conductivity employed in the solution, is estimated by means of a modified version of an asymptotic weighting scheme. The modified scheme avoids the smearing of steep wetting fronts and does not create oscillations for gravity-dominated flow, and is therefore appropriate for flow problems in highly heterogeneous flow systems associated with steep gradients or saturated regions.

The numerical scheme employed for the solution of Eq. (19) is designed to minimize numerical dispersion for advection-dominated transport problems. The scheme can be utilized even in the purely advective case ($Pe \rightarrow \infty$), where Pe is the grid Péclet number, introducing some limited numerical dispersion that smears a sharp concentration front (e.g., $c = 1$ to $c = 0$ step) over ~ 3 numerical cells in the 1-D case. The iterative scheme used to couple the $m = 3$ sets of Eq. (19), and the iterative solution method needed because of the coupling between the flow equation and the transport equations through the dependence of $K(\psi)$ and $\theta(\psi)$ on C_0 and R , are described elsewhere (Russo et al., 2004).

A case study

The physical domain and the simulated flow scenario

The case study considered here involved a citrus orchard planted on a structured clay soil in a region with typical Mediterranean climate characterized by a distinct rainy period during the winter and a long dry season over the rest of the year that necessitates multiple irrigation events. Realistic features of the flow domain, taken into account in the simulation, include the irrigation water quantity and quality, the spatial pattern of the irrigation system at the soil surface, the spatial variability of the relevant soil properties and the flow-controlled attributes, the spatial pattern of the trees' roots, and the time-dependent atmospheric forcing conditions imposed on the soil surface.

The flow scenario started at the beginning of the irrigation season (April 1st) and proceeded for 1 year. The irrigation water has moderate values of chloride concentration, $C = 10$ meq/l, and sodium adsorption ratio, $SAR = 5.7(\text{meq/l})^{1/2}$, while the rainwater has small values, i.e., $C = 1.4$ meq/l, and $SAR = 0.5(\text{meq/l})^{1/2}$. A pulse ($t_0 = 0.05\text{d}$) of a tracer solute was applied during the first irrigation event.

Results and discussion

Following Russo (2013), profiles of the horizontally-averaged mean and standard deviation (SD) of the chloride concentration, C , and the soil ESP = $f(h, SAR, C)$, for three elapsed times, for both the interacting and the inert cases, are depicted in Fig. 8a and b. These times correspond to the middle of the irrigation season, the transition period between the irrigation season and the rainy season, and the end of the rainy season, respectively. Fig. 8a suggests that the differences between the sets of both the mean and the SD profiles of C are minimal during the transition period. Most significant differences between the two sets occur during the rainy season. At the end of this season, in the inert reference case, the mean C profiles exhibit the symmetrical Fickian distribution with concentration at the soil surface that approaches its counterpart under rainwater. In contrast, for the interacting case, the mean profiles, and, particularly, the SD profiles, exhibit shallower concentration peaks, and, significant secondary concentration peaks close to the soil surface.

Fig. 8b demonstrates that the Na/Ca exchange is a very slow process compared to solute movement (Fig. 8a). This stems from the nonlinearity of the Na/Ca exchange isotherm, which, in turn, increases with increasing SAR and decreasing C . Consequently, both the increase in the soil ESP during the irrigation season, and the decrease in the soil ESP during the rainy season are confined to the upper part (≈ 1 m) of the soil profile. Fig. 8b suggests that the differences between the two sets of the profiles of the mean and the SD of the soil ESP are most substantial during the rainy season. In the inert case, both the mean and the SD of the soil ESP close to the

Fig. 8 Profiles of the mean values and the standard deviations (SD) of the soil solution chloride concentration, C , (a) and the soil exchangeable sodium percentage, ESP (b), for different elapsed times. Fig. 9 Profiles of the mean values and the standard deviations (SD) of the soil hydraulic conductivity, K , for different elapsed times. Reproduced from Russo D (2013) Consequences of salinity-induced-time-dependent soil hydraulic properties on flow and transport in salt-affected soils. *Procedia Environmental Sciences* 19: 623–632, <https://doi.org/10.1016/j.proenv.2013.06.071>.

soil surface decrease substantially during the rainy season, while their counterparts associated with the interacting case only slightly decrease.

Profiles of the horizontally-averaged mean and SD of the soil hydraulic conductivity, K , at three elapsed times (as in the previous figures) are depicted in Fig. 9; profiles of the mean and the SD of K associated with the concentration-dependent flow system (solid lines) are compared with their inert, reference counterparts (dashed-dotted lines). Fig. 9 demonstrates the substantial decrease in the mean K with increasing time, particularly in the upper part of the soil profile. Because the effect of the SS-SM interactions on the soil PSD is enhanced by a combination of low-concentration and high-SAR soil solution, the decrease in the mean K is particularly substantial during the rainy season, when the soil solution is diluted of salts, and less during the irrigation seasons when salts in the soil solution are more concentrated.

The movement and spread of a tracer solute in the spatially heterogeneous soil may serve as a measure of the capability of the soil to transfer water and solutes. Important characteristics of the tracer transport are the time-dependent, spatial moments of its concentration field, which, in turn, provide measures of the mass, location and spread of the tracer plume. The first normalized spatial moment about the origin, defines the coordinate location of the centroid of the tracer solute, $R_i(t)$, ($i = 1, 2, 3$), and is used to define the effective solute velocity vector, $\underline{V}_i$, as the time rate of change of the displacement of the centroid of the tracer

Fig. 10 Longitudinal component of the tracer solute effective velocity, V_1 , (a), and mean solute tracer flux concentration, C_f , at a horizontal CP located at vertical distance, L_1 , from the injection zone at the soil surface (b), as functions of time. Reproduced from Russo D (2013) Consequences of salinity-induced-time-dependent soil hydraulic properties on flow and transport in salt-affected soils. *Procedia Environmental Sciences* 19: 623–632, <https://doi.org/10.1016/j.proenv.2013.06.071>.

solute, i.e., $\underline{V}(t) = [dR_1/dt, dR_2/dt, dR_3/dt]^T$. The longitudinal component of $\underline{V}$, V_1 , is depicted as a function of time in Fig. 10a for both the inert and the interacting cases. The decrease in $V_1(t)$ associated with the interacting case as compared with the inert case, is attributed to the reduction in the hydraulic conductivity caused by the rearrangement of the soil's PSD; clearly the effective solute velocity substantially decreases after the first few rainstorms during the rainy season.

Another characteristic tracer transport relationship is the solute mean breakthrough curve (BTC). Consider the case of an instantaneous pulse of unit-mass, uniformly injected at the soil surface. The tracer solute mean BTC at a given horizontal control plane (CP) located at distance, L , from the soil surface, represents the travel time, τ , probability density function (PDF), $f(\tau; L)$, which, in turn, is a global descriptor of the response of the flow system to a contamination or salinization event. Mean solute tracer BTC as a function of time is depicted in Fig. 10b for both the inert and the interacting cases. This figure clearly demonstrates that changes in the transport properties of the soil related to soil sodification coupled with diluted soil solution, lead to a highly skewed mean solute tracer BTC, which exhibits an exceedingly large tail.

It should be emphasized that the effect of the SS-SM interactions on the soil hydraulic properties is essentially reversible. The relatively concentrated soil solution during the irrigation season may compensate in part for the negative effects of the SAR, which, in turn, increases slowly. As a result, the soil hydraulic conductivity may recover during the irrigation seasons. This reversible, cyclic behavior, however, may persist as long as the soil ESP does not exceed a soil-dependent, threshold value, ESPc. When the soil ESP exceeds ESPc, a breakdown of the clay particle domains, and the subsequent relocation of the clay particles, may lead to a continuous decrease in the soil hydraulic conductivity. Eventually, this may lead to an unrecoverable situation in which most of the soil surface is essentially sealed.

Concluding remarks

Salinity has many physical impacts on soil, particularly when the clay fraction is dominated by smectite minerals (e.g., montmorillonite), with solutions containing Na, Ca and Cl ions. These conditions are used in this article, with the analysis based on several simplifying assumptions, considering processes and entities at three different length-scales: (i) the micro (pore) scale, i.e., the physicochemical interactions between the soil solution and the soil matrix, the structure of the clay particles, and the soil PSD; (ii) the local (Darcy) scale, i.e., water flow and solute transport and the constitutive relationships for unsaturated flow; (iii) the field scale, i.e., the spatial structure of the heterogeneous soil and the statistics of relevant soil properties and flow-controlled attributes.

The results of the analysis presented in this chapter suggest that SS-SM interactions may alter the geometry of the soil pores, and, thus may affect the soil hydraulic conductivity, $K(h)$, and soil water retention, $\theta(h)$, functions. The effect of these interactions on $K(h)$ and $\theta(h)$, the retardation factor, R_f , and the elution factor, E_f , and, concurrently, on water flow and solute transport may be significant. This effect generally increases as the soil solution's sodium adsorption ratio (SAR) increases; as both the soil solution concentration and the capillary pressure head decrease; as the clay fraction of the soil increases; and as the soil-texture becomes finer.

The case study and the results of the simulations presented in this chapter are relevant to fine-textured soils whose clay fraction is dominated by montmorillonite. The results of the simulations suggest that enhanced SS-SM interactions, induced by increasing soil exchangeable sodium during the irrigation season and dilution of the soil solution during the rainy season, may considerably reduce soil hydraulic conductivity during the rainy season, particularly, close to the soil surface, and, concurrently, may reduce water velocity. Consequently, enhanced SS-SM interactions, may greatly slow down the solute movement, may substantially increase the tailing of the mean solute breakthrough at a given horizontal control plane (CP), and may change markedly the pattern of the solute concentration profiles.

Inasmuch as the effect of the SS-SM interactions on the soil hydraulic properties is essentially reversible, the relatively concentrated soil solution during the irrigation seasons may compensate in part for the negative effects of the SAR, which, in turn, increases slowly; consequently, during the irrigation seasons, the soil hydraulic conductivity may recover. This reversible, cyclic

behaviour, however, may persist as long as the soil ESP does not exceed a soil-dependent, threshold value, ESP_c . Additional simulations (not shown here) suggest that the value of ESP_c was not reached during a period of 7 years, allowing the aforementioned cyclic behaviour to persist. This is expected in view of the values of C and SAR employed in the simulations, which, in turn, are typical of treated-wastewaters used for irrigation.

Abstract

Soil shrinking and swelling with water, leading to crack formation, is the primary abiotic soil structure forming process. Shrinking is mostly due to the soil colloids forming the soil *plasma*, which produces a characteristic shrinkage curve (SC) on drying. Soil shrinkage has physical, geotechnical and pedological applications with relevance to (i) its impact on soil hydrodynamics (preferential flow in cracks and changes in the hydraulic characteristics) and (ii) improved impact diagnosis and upscaling of physical properties by deterministic SC modeling. In natural soils, organic matter and aggregation affect shrinkage and therefore the development of soil structure by drying and wetting.

Glossary

COLE Coefficient of linear extension.

Plasma That part of the soil solid material that is easily deformed, reorganized or concentrated by the processes of soil formation. It includes all the material, mineral or organic, of colloidal size and relatively soluble material that is not contained in the skeleton grains.

Structural porosity Pore system made of the biopores, the cracks and the packing voids.

Key points

- All soils containing colloids show a shrinkage curve
- The characteristic shrinkage curve (SC) on drying should be considered in the hydrodynamics of non-rigid soils
- SC deterministic modeling allows characterization of the plasma and structural pore systems
- SC analysis allows improvement in the soil physical characterization of the soil
- Applications in hydrodynamics: non-rigid soils, by-pass flow
- Applications in structure characterization, compaction diagnosis
- Spatialization and dynamics of soil physical properties

Introduction

Most soils show shrink-swell behavior, induced by the forces resulting from changes in water content and their impact on pore volumes. The extent of soil shrinkage is generally defined as the bulk density or specific volume change of soil relative to its water content (Haines, 1923). It is, therefore, a physical property of undisturbed soil structure that has a large impact on a range of soil processes, especially pore structure dynamics and transport. The volume change with water content is due to the shrinking and swelling of soil constituents and their structural arrangement.

Soil shrinkage has been studied for more than a century and was first considered as an indicator of soil structural stability. It is evident in some soils by the creation of cracks, which is considered as the primary and major abiotic process of soil structure

formation (see Soil Structure section). Vertisols, for instance, shrink extensively during drying, which provides one of the key diagnostic features of their classification. During the 20th century, the scope of interest in soil shrinkage widely increased in soil science and civil engineering. In engineering applications, the question is mostly related to heavy swelling-clay soils whose shrinking properties may severely damage buildings. In soil science, the investigations covered a wide range of topics, ranging from a fundamental understanding of pedogenic processes to applications in understanding water flow, structural stability or pore structure dynamics. Soil scientists have explored the role of soil constituents in soil shrinkage, observing a characteristic shrinkage curve (SC) that relates specific volume (or bulk density) of the soil to its water content. Using the shrinkage curve in modeling and analysis has applications in soil physics and soil physical characterization from the aggregate to field scale. There is capacity with soil shrinkage modeling to bridge the knowledge on soil fabric, soil constituents and soil hydrodynamics. In shrinking soils, hydrodynamics is affected by both matric potential draining soil pores and changes to the size of pores from shrinkage. Although the former process is studied extensively in soil physics, the second process is often overlooked, so soil shrinkage modeling plays an important role in overcoming a major limitation faced by soil physics.

Origin of soil shrinkage

If we revisit the example of Vertisols, their large macroscopic shrink-swell behavior is closely related to their large content of swelling clays (see Pedology section in this Encyclopedia). Seasonally dependent crack networks develop in these soils with cycles of wetting and drying. Smaller concentrations of swelling clays and other colloids observed in other soils results in less shrinkage, leading to smaller size cracks whose network may only be observable on thin sections. Mineral soils are formed of voids, skeleton grains, and colloids, namely clay minerals bound to soil organic carbon (SOC) and oxides forming the soil *plasma* (*"Glossary of Soil Science Terms | Soil Science Society of America,"*, 2020). The plasma consists primarily of domains of silt- and clay-size particles coated with SOC and oxides. It comprises small (nm to μm) interparticle pores. Because clay particles are major constituents of the plasma, it is also referred to as the clay matrix, clay phase, or organo-mineral complex. Clay minerals and SOC shrink and swell with changes in water content. The shrinkage behavior of clay pastes has been well described and depends on the clay mineral properties (e.g., Tessier, 1990). The shrinkage of the soil, therefore, depends on the clay content, clay type, SOC and oxides acting as binding elements, thus limiting the shrinkage of the plasma (Boivin et al., 2009, 2004; Goutal-Pousse et al., 2016).

As a structured medium, the soil has a porosity. Various classifications of soil pores based on size classes have been proposed (see Soil Structure section). Size classes are user, tool, and scale dependent. Therefore, they do not reflect intrinsic properties of the structured soil and its materials. Soil shrinkage occurs at the expense of soil porosity and is, therefore, related to the nature and behavior of the soil pores. Soil pore size distribution, shape, and connectivity have been investigated for their implications in transport properties or as habitat of soil biota. At its simplest, a rigid, homogeneous, and uniform pore network has been assumed in water transport modeling, but structural complexity of the pore network has become increasingly appreciated and feasible to model with higher speed computers. The deformation of the structure, especially its changes due to shrinkage, is often overlooked.

The solid material (either minerals or organic matter) and pore system together constitute the soil fabric. The physical structure of the soil fabric was long ago described by micromorphologists (e.g., Brewer, 1964), which allowed identification of two categories of soil pore systems, based on their origin, shape and function; namely the structural pores and the plasma pores. Plasma pores are equivalent to textural porosity, which refers to the clay pores and the lacunar voids between skeleton grains and the clay matrix. Taking this approach, the structural porosity includes cracks, biopores, packing voids and vughs. Because of their origin, plasma pores are sub- μm , while the volume of structural pores is mostly represented by pores larger than $5\ \mu\text{m}$.

The structural and plasma pores show distinct shrink-swell behavior upon changes in soil water content. From saturation to the *Air Entry* (AE) point, no air entry occurs in plasma pores (Tessier, 1990). Therefore, the plasma pores remain saturated along the corresponding water content range, and the clay paste volume follows a 1:1 line with the water content (Fig. 1), until AE is reached,

Fig. 1 Schematic shrinkage curve of a clay paste.

which may account for a large soil shrinkage in swelling clay soils. In contrast, air enters into the structural pores upon soil drying, and water menisci exert a shrinkage pressure on the soil by Jurin's law of capillarity and approximated by the Laplace equation.

Basics of soil shrinkage

Soil shrinkage was studied early in the early 20th century for its impact on soil structure, including disputed roles of colloidal coatings (Haines, 1923; Hardy, 1923). Later, soil shrinkage was investigated for geotechnical problems like foundation integrity or in soil science as an indicator of structure stability (McGarry and Daniells, 1987). The concept of linear extensibility was introduced to characterize the one-dimension change of soil with water content, which is usually quantified with the Coefficient of Linear Extensibility (COLE) (Grossman et al., 1968):

$$COLE = \frac{L_m}{L_d} - 1 \quad (1)$$

where L_m is the length of the moist soil unit and L_d is the length of the dry soil unit. COLE indicates the potential of the soil to shrink and swell with water. As the extent of shrinkage can result in soil layer cracking and soil subsidence, there is a great interest in measuring COLE for engineering or preferential flow modeling (Coppola et al., 2015). COLE is used in soil classification to categorize shrinking soils such as Vertisols, which require at least 0.06 mm m^{-1} linear shrinkage in their characterization. Testing of COLE is simple. It involves filling a trough of soil with a remolded soil paste and then measuring the length change after the soil has been dried. However, shrinkage is a volumetric, so the volume change is related to the COLE by:

$$\frac{dV}{V} = \left(\frac{dL}{L}\right)^n \quad (2)$$

with V , the soil specific volume ($\text{cm}^3 \text{g}^{-1}$), L the soil length, and n the geometric factor (Towner, 1986) with $n = 3$ in case of isotropic shrinkage.

Using a remolded paste, however, destroys soil structure. Because of the strong relationship between soil structure and soil SC, COLE is much more descriptive of realistic field conditions if it is measured on undisturbed soil, contrary to what is sometimes practiced in geotechnical engineering for clayey materials.

COLE measures the extremes of shrinkage between maximum wetness and dryness. The availability of quasi continuous SC measurement techniques over a range of water contents on undisturbed soil cores allows for the general shape of the soil SC to be split into different linear domains with curvilinear transitions (Braudeau et al., 2004) (Fig. 2). These main domains, from water saturation to air dry, are the structural, basic and residual shrinkage domains. In some soils, however, an additional swelling domain is observed close to water saturation and was interpreted as a property of poorly aggregated soil. Another sharp shrinkage domain has been observed near to the air-dry state in Swiss and Canadian soils with large SOC content (unpublished). Despite these possible additional domains at the two ends of the SC, most of the water content change is observed from structural to residual

Fig. 2 Cambisol shrinkage curve showing the typical S shape, soil shrinkage domains, water saturation line and distribution of air and water in the pore systems.

shrinkage. The magnitude of these domains depends on soil type and colloid content, though the S-shape is characteristic of many soils, e.g., in Vertisols, Calcisols, Cambisols, Luvisols, Ferralsols etc.

The structural shrinkage occurs primarily due to the drainage of structural pores. Its slope has been related to soil structural stability since it depicts the capacity of the structure to withstand the menisci forces. The basic shrinkage (Fig. 2), also referred to as proportional shrinkage (Mitchell, 1992), is related to the proportional shrinkage of the clay. For clay, this slope is equal to 1 (Fig. 1), but for structured soil it usually ranges from less than 0.1 to more than 1.5, depending of the tendency of the structure to collapse or to remain rigid upon plasma shrinking. Therefore, for the same plasma shrinkage, the lower the soil shrinkage slope, the denser the crack network in the soil and the greater its volume.

Shrinkage measurement

Soil shrinkage can be measured in situ using displacement transducers that record the movement of gauges inserted at different depths (Coquet et al., 1998), though this is technically demanding and difficult to interpret. However, shrinkage is mostly measured on extracted undisturbed cores or clods. Once soil is removed from its environment, however, the overburden pressures of the overlying soil layers is not accounted for. Different devices have been proposed in the last decades to measure the shrinkage of clods, allowing high accuracy and quasi continuously measurement of SC. Examples include laser barriers (Braudeau et al., 1999), displacement transducers (Fig. 3) (Boivin et al., 2004; Schindler et al., 2015) and X-Ray CT (Peth et al., 2010). Linear or circumference changes are converted into volume change using Eq. (2), with estimation of the geometric factor when the soil wet and dry volumes are measured. The geometric factor of soil cores has been generally reported to be close to 3 on average, though its value changes along the SC (Boivin, 2007).

Shrinkage modeling

Shrinkage modeling was performed early in soil science, with the aim of quantifying the structural stability of the soil. In past decades models were proposed that took benefit from the high quality SCs obtained with quasi-continuous SC measurement devices. Two categories can be distinguished. One category of equations aims to reproduce quantitatively the SC, for instance to account for its influence on hydraulic conductivity (Horn et al., 2014). Due to the characteristic S-shaped curve of the SC, one approach modified the Van Genuchten equation. Another category is deterministic models based on considerations of the nature and behavior of soil pores, accounting for the properties of plasma and structural pores with decreasing water content, as presented above. In the first category of equations, the number of parameters conditions the ability of the model to reproduce the observation, which opposes the objective of using a minimum number parameter.

Deterministic models have been proposed from particle scale to layer scale, with special emphasis on clod scale. The most developed models (Braudeau et al., 2004, 1999; Chertkov, 2012) are based on common concepts, namely soil SC accounting for the combined effect of shrinkage of plasma (that can be referred to as clay matrix or microporosity) and structural pores. The shrinkage of plasma is considered, as depicted in Fig. 1, and that of the structural porosity, including cracks, drains with soil drying with limited deformation, being accounted for by the slope of the structural shrinkage (Fig. 2). To our best knowledge, model comparisons have rarely been performed on high resolution SCs (Boivin et al., 2006), therefore, we will not discuss this aspect further.

In Boivin (2007), the clay pastes sub-model of Chertkov (2012) and Braudeau et al. (1999) were found to be extremely close, thus implying a similar modeling of the complementary structural porosity volume for successful fitting. However, only the XP model (Braudeau et al., 1999) has been successfully applied to a large number of undisturbed sample series from different soil types. The thermodynamic formalism of the soil shrinkage proposed by Braudeau et al. (2014) is based on previous research starting with Sposito (1972). Based on the two-pore systems description, it yields results close to those obtained with XP. Note that overburden is not taken into account in this model, thus applicable to isolated soil structure units.

Fig. 3 Undisturbed cambisol sample shrinking from -10 hPa (left) to air-dry (right) in a shrinkage apparatus (Schäffer et al., 2008). Note the displacement transducer on the top of the sample (picture C. Deluz).

Properties and processes affecting shrinkage curves

Soil shrinkage is affected by clay type, clay content, iron and aluminum oxides, SOC content (see above) and carbonate content (Zolfaghari et al., 2016). These factors show linear relationships with the shrinkage parameters as determined with the XP model, or modified Van Genuchten equation of shrinkage. For instance, shrinkage increases with clay content and decreases with SOC and iron oxides contents, whereas the structural pore volume and the readily available water increase with SOC content. In that respect, the spatial variability of soil colloids allows one to account for the spatial variability of soil physical properties. Moreover, the coefficients of variation (CV) of the SC parameters (XP model) are very small (from 7% to 14%, Boivin, 2007; Boivin et al., 2006) compared with CVs for most soil physical parameters reported, thus opening the door to effective mapping of the soil shrinkage properties and derived pore systems parameters.

Soil shrinkage is also affected by external factors such as cropping practices, trafficking or biological activity, and shrinkage modeling has been used to determine structure degradation indicators (Johannes et al., 2019), to characterize tillage effects (Mallory et al., 2011), soil compaction (Peng et al., 2009) and structure recovery (Fell et al., 2018; Goutal-Pousse et al., 2016), or the effect of soil biota on soil structure (Milleret et al., 2009). Fitting XP on soil SCs allowed a distinction to be made between the effect of soil constituents, their variability, and factors such as trafficking on biological activity, thus allowing for improved field diagnosis.

Significance

Many developments in soil physics require assumptions about the pore network, such as homogeneity and rigidity, to simplify the numerical solution of the equations. These assumptions oppose the known behavior of structured soils containing colloids, i.e., non homogeneous and uniform pore network, and geometry changes with water content. This has raised many issues in application, particularly in parameter estimation and mapping. The physical properties, as determined according to mechanics theories, exhibit large variability, unstable variances with measurement device size, and poor correlation with the distribution of soil constituents. The developments of pedotransfer functions (Bouma and van Lanen, 1987) are aimed at bridging the resulting gap between soil physical properties and easy to map soil properties, in particular colloid content, by establishing local correlations. To some extent this can be considered doomed to failure owing to the fundamental contradiction between soil mechanics assumptions and soil properties. With that respect, one may consider the development of shrinkage modeling as a promising way to bridge this gap.

Fluid transfer modeling equations including the shrink-swell properties of the soil were proposed (Garnier et al., 1997). However, the soil volume change with water remains seldom considered in fluid transfer modeling despite its strong impact (Horn et al., 2014). The introduction of shrink-swell properties in water transfer models allows the dynamic accounting of preferential flow at layer scale (Coppola et al., 2015). A full modeling method including (i) overburden (Smiles and Raats, 2005), (ii) preferential flow in cracks and (iii) the dual porosity (accounting for transfers between plasma aggregates and structural pores) is still to be formulated.

Significant progress in soil structure characterization has been gained with shrinkage analysis. In the context of climate change, and SOC depletion leading to poor quality soils, it is of key importance to improve our capacity to monitor and model changes in soil physical properties. For instance, shrinkage analysis allowed to emphasize the role of SOC in soil structure and soil porosity development (Boivin et al., 2009), to propose improved soil compaction diagnosis (Goutal-Pousse et al., 2016; Schäffer et al., 2008) and effective structure degradation indicators (Johannes et al., 2019).

Perspectives

In re-designing water transfer models at profile scale, taking into account soil shrinkage is essential. Addressing this challenge requires growing interest in developing deterministic shrinkage models, which include the two-soil pore-systems (structural and plasmic) and their response to changes in soil constituents (particularly SOC content). This opens the door to models that are capable of dynamic adaptation of soil physical properties to, e.g., soil management, and to sharply improve model parameter specialization.

To do so, research is needed that can fill the known and suspected knowledge-gaps remaining. For example, the deterministic models of shrinkage include a transfer of water from plasma porosity to structural porosity, which needs to be further investigated (Barbosa et al., 2022), and overburden should be included in the description of water potential and confining stresses from the surrounding soils that would be found in the field.

Another perspective is to improve our understanding of soil complex processes. The role of structural porosity in microorganism activity and the related carbon or nitrogen cycles has started to be deciphered, in particular with imaging technology (Kravchenko et al., 2019). Changes to soil pore structure with shrinkage is likely to have a large impact on microbial habitats, activity and physical protection. Such a fundamental knowledge is key to our understanding of soil ecosystem services management, particularly in cropland, but it is hard to study in situ and at large scale. On the other hand, shrinkage analysis does not allow the capture of fine structural pores architecture, but it does allow precise, inexpensive quantification of fine structural pore volume, size distribution,

and their relationships with constituents and practices at large scale. Therefore, research on the links between fine structural porosity architecture and the shrinkage signature of soil structure should be worked out. The impacts extend beyond physical processes, including the capacity of soil pores to support biological activity and diversity, but shrinkage impacts have been overlooked.

Finally, though deterministic modeling of soil SC seems more promising, the models are based on assumptions that have been only partially validated, at best. If the above perspectives stand, it is of critical importance to progress in deterministic SC modeling associated with a fully validated physical formalism of the underlying processes.

Abstract

The ubiquity of water in our living world is briefly surveyed. Fundamental properties of water are described from atomic to bulk scales, including water molecular structure; unique role of hydrogen bond in water molecular structure; thermodynamic conditions defining water phases; stable and metastable states, and phase transitions; interaction of water and dissolved ion; dissolutions of gasses in liquid water; dependence of vapor pressure on temperature in the presence of liquid water or ice; soil water retention mechanisms of adsorption and capillarity; and water and soil water's macroscopic physical properties of density, compressibility, and dynamic and kinematic viscosity.

Key points

- The ubiquitousness of water in our living world is briefly surveyed.
- Fundamental properties of water are described from atomic to bulk scales, including water molecular structure; unique role of hydrogen bond in water molecular structure; thermodynamic conditions defining water phases; stable and metastable states, and phase transitions; interaction of water and dissolved ion; dissolutions of gases in liquid water; dependence of vapor pressure on temperature in the presence of liquid water or ice; soil water retention mechanisms of adsorption and capillarity; and water and soil water's macroscopic physical properties of density, compressibility, and dynamic and kinematic viscosity.

Introduction

Our Earth is the planet of life, primarily because it is blessed with the precise ranges of temperature and pressure that make possible the existence in a liquid state of a singular substance called water. So ubiquitous is water on our globe, covering nearly three-quarters of its surface, that the entire planet really should be called 'Water' rather than 'Earth.' However, as Coleridge's Ancient Mariner complained, most of the water everywhere is unfit to drink. Less than 2.5% of the water on earth is 'fresh' (i.e., non-saline) water, and that amount is spatially and temporally unevenly distributed. Humid regions are endowed with an abundance of it, even with a surfeit, so that often the problem is how to dispose of excess water. Arid and semiarid regions, on the other hand, are afflicted with a chronic shortage.

[†]Deceased

Life as we know it most likely began in an aquatic medium and water is still the principal constituent of living organisms. Water is, literally, the essence of life. As Vladimir Vernadsky (1863–1945) wrote a century ago: “Life is animated water.” Though we appear to be solid, we are really liquid bodies, similar to gelatin, which also seems solid but is in fact largely water, made consistent by the presence of organic material. The analogous material in the cells of our bodies is protoplasm. The water content of a newborn infant is nearly 75% water by mass, and even in adults it is over 55%. Actively growing herbaceous plants typically contain over 90% water. Far from being a bland, inert liquid, water is a basic reactant substance, a powerful solvent and an effective transporter of numerous substances.

The importance of water was recognized early in history, yet little was known about its real nature. In the Middle Ages, people believed that fresh water emanated magically from the bowels of the earth. They could not imagine that all the water flowing in innumerable springs and mighty rivers (such as the Nile, which appeared to the ancient Egyptians to come out of the driest desert!) could possibly result from so seemingly feeble a source as rain and snow. The first to conjecture this was Leonardo da Vinci, but only in the latter part of the 17th century did the English astronomer Edmond Halley and, separately, the Frenchman Claude Perrault prove the principle by calculation and measurement. Water was long thought to be a single element, until early in the 18th century, when it was found to consist of hydrogen and oxygen in combination.

Notwithstanding its ubiquity, water remains something of an enigma, possessing unusual and anomalous attributes. Perhaps the first anomaly is that, being a compound of two elements and having relatively low molecular weight, water co-exists as liquid and vapor at room temperature. (Its sister compound, hydrogen sulfide, H_2S , has a boiling-point temperature of -60.7°C .) Compared with other common liquids, water has unusually high melting and boiling points, heats of fusion and vaporization, specific heat, dielectric constant, viscosity, and surface tension.

Molecular structure

One cubic meter of liquid water at 20°C and 1 atm pressure (101.3 kPa) contains about 3.7×10^{28} (37 billion billion billion) molecules, the diameter of each is about 2.75×10^{-10} m (2.75×10^{-1} nm, or about 2.75 Angstrom units). The chemical formula of water is H_2O , which signifies that each molecule consists of two atoms of hydrogen and one of oxygen. There are three isotopes of hydrogen (^1H , ^2H , ^3H) and three of oxygen (^{16}O , ^{17}O , ^{18}O), which can form 18 combinations. However, all isotopes but ^1H and ^{16}O are quite rare.

The hydrogen atom consists of a positively charged proton and a negatively charged electron. The oxygen atom consists of a nucleus having a positive charge of eight protons, surrounded by eight electrons, of which six are in the outer shell. Since the outer electron shell of hydrogen lacks one electron and that of oxygen lacks two electrons to satisfy quantum stability, one atom of oxygen can combine with two atoms of hydrogen in an electron-sharing molecule.

The strong intermolecular forces in liquid water are caused by the electrical polarity of the water molecule, which in turn is a consequence of the arrangement of electrons in its oxygen and hydrogen atoms (Fig. 1). The oxygen atom shares a pair of electrons with each of the two hydrogen atoms, through overlap of the 1 s orbitals of the hydrogen atoms with two hybridized sp^3 orbitals of

Box 1

A Farewell to Teardrops.

For centuries, conventional wisdom held that larger stones fall faster than small ones, that the Earth is flat yet the sun revolves around it, and that the sun and moon are of equal size. We would like to believe that in our time all baseless notions have been replaced by sound science. But have they?

Consider the shape of a raindrop. The conventional standard is a teardrop, rounded at the bottom and tapering to a point at the top (Fig. B1). So prevalent is that image that it is printed in textbooks and used as a logo by irrigation companies and even by conferences sponsored by the United Nations. Alas, the vertically elongated, top-pointed raindrop is a physical impossibility.

A drop forming at the tip of a spout assumes that shape only at the very instant of detachment. Because of surface tension, any drop suspended in air ‘balls up’ spontaneously into a sphere. In a cloud, spherical droplets tend to grow by condensation or coalescence until reaching a critical weight equal to the buoyant force provided by the surrounding air, over which they begin to fall.

Air bypassing a falling drop acquires greater velocity around the curved ‘waist’ of the drop than near its top or bottom. By Bernoulli’s law ($p + \rho v^2/2 = \text{constant}$), the pressure of the air alongside the drop is lowered relative to that of the air above and below the drop. Consequently, the drop compresses vertically and comes to resemble an ellipsoid. Such is indeed the shape of small drops (<2 mm).

In the case of larger drops, the laminar streams of air flowing past the drop may not converge smoothly above the top, but may leave a turbulent wake there. In such a wake, the pressure is lower than it would be in an ideally laminar flow regime. The reduced air pressure at the top causes the drop to bulge a bit there, thus acquiring the appetizing shape of a miniature hamburger bun (described by the appropriately named McDonald as early as 1954).

If a drop were to continue accelerating, it might eventually spread out to form a pancake. But Stokes’ law intervenes, decreeing that the drop’s acceleration be countered by the increasing viscous resistance of the air. When air resistance equals the gravitational force, acceleration ceases and the drop continues to fall at a constant ‘terminal’ velocity and with a more or less constant shape. It finally slaps the ground with its flattened face going ‘plop’.

Some of us may think it unfair that such an exquisitely sculpted natural body should have no more glorious a fate than to splatter down on some dry bit of earth. But that is where—having at once lost its distinctive shape as it enters the labyrinthine interstices of the soil—our drop might well give life to a thirsty plant, perhaps even to a sunflower. Anyhow, we bid farewell to the sad countenance of the teardrop, a singularly inappropriate symbol for happy rain.

**Fig. B1** Conventional and real raindrops (Hillel, 1998).**Fig. 1** Model of a liquid water molecule (Hillel, 1998). The curved lines represent the borders at which van der Waals attractions are counterbalanced by repulsive forces.

the oxygen atom. The H—O—H bond in water is not linear but bent  at an angle of 104.5° . That angle deviates slightly from the perfectly tetrahedral arrangement of the oxygen atom's four possible sp^3 orbitals, which would have an angle of 109.5° . The mean H—O interatomic distance is 9.57×10^{-2} nm. The arrangement of electrons in the molecule gives it electrical asymmetry or polarity. The electronegative oxygen atom tends to attract the single electrons of the hydrogen atoms, leaving the hydrogen nuclei bare. Hence, each of the two hydrogen atoms has a local partial positive charge. The oxygen atom, in turn, has a partial negative charge, located in the zone of the unshared orbitals. Thus, though the water molecule has no net charge, it forms an electrical dipole.

Hydrogen bonding

Every hydrogen proton, while attached primarily to a particular molecule, is also attracted to the oxygen of the neighboring molecule, with which it forms a secondary link known as a hydrogen bond. Though the intermolecular link resulting from dipole attraction is not as strong as the primary link of the hydrogen to the oxygen of its own molecule, water can be regarded as a polymer of hydrogen-bonded molecules. This structure is most complete in ice crystals, in which each molecule is linked to four neighbors via four hydrogen bonds, thus forming a hexagonal lattice with a rather open structure (Fig. 2). When the ice melts, this rigid

Fig. 2 Schematic structure of an ice crystal (Hillel, 1998). The oxygen atoms are shown in gray and the hydrogen atoms in white. The pegs linking adjacent molecules represent hydrogen bonds.

structure collapses partially, so additional molecules can enter the intermolecular spaces and each molecule can have more than four near neighbors. For this reason, liquid water can be denser than ice at the same temperature, and thus the ice sheet formed on the surface of lakes and ponds in winter remains on the top rather than sinks to the bottom as it would if ice were denser than liquid water.

States of water

In the vapor or gaseous state, water molecules are largely independent of one another and occur mostly as monomers signified as $(\text{H}_2\text{O})_1$. Occasionally, colliding molecules may fuse to form dimers $(\text{H}_2\text{O})_2$ or even trimers, $(\text{H}_2\text{O})_3$, but such combinations are rare. However, in the solid state a rigidly structured lattice forms with a tetrahedral configuration (Fig. 2) that can be schematically depicted as sheets of puckered hexagonal rings (Fig. 3). As many as nine alternative ice forms can occur when water freezes,

Fig. 3 The crystalline structure of ice I (Hillel, 1998).

depending on prevailing temperature and pressure conditions. Fig. 3 pertains to ice I, the familiar form, which occurs and is stable at ordinary atmospheric pressure.

The orderly structure of ice does not totally disappear in the liquid state. The polarity and hydrogen bonds continue to bind water molecules together, though the structural forms that develop in the liquid state are much more flexible and transient than in the rigidly structured solid state. Hydrogen bonds in liquid water form an extensive three-dimensional network, the detailed features of which appear to be short-lived. According to the 'flickering cluster' model discovered by Frank and Wen and modified by Erland, the molecules of liquid water associate and dissociate repeatedly in transitory or flickering polymer groups, designated $(\text{H}_2\text{O})_n$, having a quasicrystalline internal structure. These microcrystals, as they were, form and melt so rapidly on the scale of picoseconds and randomly that, on a macroscopic scale, water appears to behave as a homogeneous liquid (Fig. 4).

What determine water phases are pressure and temperature (Fig. 5). In transition from ice to liquid (fusion) and from liquid to vapor (vaporization), hydrogen bonds must be broken (while in freezing and condensation they are re-established). Hence relatively high temperatures and energies are required to achieve these water phase transitions. To thaw 1 kg of ice, $3.35 \times 10^5 \text{ J}$ (80 cal g^{-1}) must be supplied. Conversely, the same energy (the latent heat of fusion) is released in freezing. At the boiling point (100°C , at atmospheric pressure), water passes from the liquid to the gaseous state and in so doing it absorbs $2.26 \times 10^6 \text{ J kg}^{-1}$.

Fig. 4 Schematic illustration of 'flickering clusters,' showing polymeric associations and monomeric molecules in liquid water (Hillel, 1998).

Fig. 5 Schematic illustration of water phase diagram in temperature and pressure (Debenedetti, 1996). Note: the pressure limits of cavitation are determined from the van der Waals equation of state.

(540 cal g⁻¹). This amount of heat is known as the latent heat of vaporization. Water can be vaporized at temperatures below 100 °C, but such vaporization requires greater heat or lower atmospheric pressure. At 30 °C, the latent heat is about 2.43×10^6 J kg⁻¹ (580 cal g⁻¹). Sublimation is the direct transition from ice to vapor, and the heat absorbed by this process is equal to the sum of the latent heats of fusion and vaporization.

Under certain pressure and temperature conditions, water is at the metastable state (Fig. 5), i.e., liquid water is cooled below the freezing point without crystallizing (supercooling) and liquid water is stretched below the saturated vapor pressure without gasifying (cavitation). Impurities like dissolved gasses and soil particles can greatly control the transition from liquid to vapor (cavitation) or conversely from vapor to liquid (condensation). Rough surfaces of soil particles often provide sites to entrap gasses that promote cavitation or to retain ice nuclei that trigger freezing. Small environmental perturbations in pressure and temperature can break the metastable states and yield spontaneous cavitation, condensation, or freezing.

Because of the existence of electromagnetic field near soil particle surface and the polarity of water molecules, water is attracted to soil particle surface and into clay lamellae, where much elevated inter-water molecular pressure is produced. Such elevated pressure could be as high in magnitude as gigapascal (GPa) for the formation of the first adsorbed layer of water molecules, leading to a depression of water freezing or supercooling temperature in soil to as low as -22 °C (i.e., 251 K in Ice III structure regime) (Fig. 5). The phenomenon of supercooling of soil water widely occurs in regions of thawing and freezing.

Water-ion interaction

Ionization and pH

Because of its small atomic mass and the tightness with which its single electron is bound to the oxygen atom, the nucleus of the hydrogen atom in the water molecule exhibits a finite tendency to dissociate from the oxygen with which it is covalently associated and to 'jump' to the adjacent water molecule, with which it is hydrogen-bonded. Such an event produces two ions: the hydronium cation (H₃O⁺) and the hydroxyl ion (OH⁻). The reaction described is reversible, and should be written as:

However, by convention it is written simply as:

and one speaks of 'hydrogen ions' rather than of 'hydronium ions.'

Although the self-ionization of water is small, its consequences are extremely important. The ionization is reversible, and it tends to an equilibrium state in which the rate of dissociation into ions equals the rate of ion reassociation to form molecules once again. For such a system in equilibrium (at which the concentration of each of the species H₂O, H⁺, and OH⁻ remains constant), the law of mass action applies; i.e., the ratio of concentrations of the products and the reactants must be constant. Using brackets to denote concentration, we can write this in the following way:

$$K_{\text{equal}} = [\text{H}^+][\text{OH}^-]/[\text{H}_2\text{O}] \quad (1)$$

Since the number of water molecules undergoing dissociation at any given time is very small relative to the total number of water molecules present, [H₂O] can be considered constant. Assuming this concentration to be 55.5 mol L⁻¹ (the number of grams per liter divided by the gram molecular weight: 1000/18 = 55.5 mol L⁻¹), we can simplify the equilibrium constant expression as follows:

$$55.5K_{\text{equal}} = [\text{H}^+][\text{OH}^-], \text{ or } K_w = [\text{H}^+][\text{OH}^-] \quad (2)$$

in which K_w is a composite constant called the ion product of water. In fact, the concentrations of H⁺ and OH⁻ ions in pure water at 25 °C are 10⁻⁷ mol L⁻¹, an extremely small value when compared to the overall concentrations of (largely undissociated) water, namely 55.5 mol L⁻¹. Thus, K_w at 25 °C is 10⁻¹⁴. If the hydroxyl ion concentration [OH⁻] is changed, the hydrogen ion concentration [H⁺] changes automatically to maintain the constancy of the product, and vice versa. An excess concentration of hydrogen ions over the concentration of hydroxyl ions imparts to the aqueous medium the property of acidity, whereas a predominance of hydroxyl ions produces the opposite property of alkalinity or basicity. A condition in which the concentrations of H⁺ and OH⁻ are equal is called neutrality.

The ion product of water, K_w , is the basis for the pH scale, a measure of the concentration of H⁺ (and of OH⁻ as well) in any aqueous solution in the range of concentration between 1.0 mol L⁻¹ H⁺ and 1.0 mol L⁻¹ OH⁻. The pH is defined as:

$$\text{pH} = \frac{\log_{10} 1}{[\text{H}^+]} = -\log_{10} [\text{H}^+] \quad (3)$$

As already stated, in a precisely neutral solution at 25 °C, the pH of such a solution is:

$$[\text{H}^+] = 1.0 \times 10^{-7} \text{ mol l}^{-1}$$

The pH of such a solution is:

$$\text{pH} = \log_{10} \left[\frac{1}{1 \times 10^{-7}} \right] = 7.0$$

The pH value of 7.0 for a neutral solution is thus not arbitrary, but derives from the value of the ion product of water at 25 °C. The pH scale is logarithmic, not arithmetic. If two solutions differ in pH by one unit, then one solution has 10 times the hydrogen ion concentration of the other. Thus, a pH of 6 implies a hydrogen ion concentration of 10^{-6} and a hydroxyl ion concentration of 10^{-8} . A pH of 5 indicates $[\text{H}^+] = 10^{-5}$ (acidity 10 times that of the above) and $[\text{OH}^+] = 10^{-9}$.

Solvent properties of water

Water dissolves or disperses many substances because of its polar nature. Hence it has been called the universal solvent. All chemical substances have finite solubilities in water, but these solubilities range widely. Many crystalline salts and other ionic compounds readily dissolve in water but are nearly insoluble in nonpolar liquids such as chloroform or benzene. Since the crystal lattice of salts, such as sodium chloride, is held together by very strong electrostatic attractions between alternating positive and negative ions, considerable energy is required to pull these ions away from one another. However, water dissolves sodium chloride because the strong electrostatic attraction between water dipoles and the Na^+ and Cl^- ions, forming stable hydrated Na^+ and Cl^- ions, exceeds the attraction of these ions to each other. In the case of Na^+ , hydration is represented by the process:

illustrated in Fig. 6. In addition to hydration, there is also the hydrolysis of metal species, a reaction in which the metal ion displaces one of the protons (hydrogen) of water to form basic hydroxides.

Ion solvation is also aided by the tendency of the solvent to oppose the electrostatic attraction between ions of opposite charges. This is characterized by the dielectric constant D , which is defined by the relationship:

$$F = \kappa e_1 e_2 / Dr^2$$

Here F is the attractive force between two ions of opposite charge, κ is Coulomb's constant, e_1 and e_2 are charges on the ions, and r is the distance between them. Water has an extremely high dielectric constant (compared to 1.0 of air), as shown in Table 1. For instance, the attractive force between Na^+ and Cl^- ions at a given distance in water is less than one-third that in ethanol and only one-40th that in benzene. This fact greatly facilitates hydration of ions and dissolution of the crystal lattices of salts in water.

Fig. 6 A model of the hydration 'atmosphere' of a sodium ion (Hillel, 1998). An inner shell of more or less rigidly structured water is surrounded by a cluster of looser but still structure-enhanced water, the whole floating in a sea of 'free' water.

Table 1 Dielectric constants of some liquids (20 °C) (Hillel, 1998).

Water	80.4	Acetone	21.4
Methanol	33.0	Benzene	2.3
Ethanol	25.3	Hexane	1.9

The effect of a solute on the solvent is manifest in a set of properties, namely, the colligative properties of solutions, which depend on the number of solute particles per unit volume of solvent. Solutes produce such characteristic effects in the solvent as depression of the freezing point and of the vapor pressure, and elevation of the boiling point. They also endow a solution with the property of osmotic pressure. Theoretically, 1 mol of an ideal solute dissolved in 1 kg of water at a pressure of 760 mm of mercury (0.1 MPa, or 1 bar) depresses the freezing point by 1.86 °C and elevates the boiling point by 0.543 °C. Such a solution also yields an osmotic pressure of 2.24 MPa (22.4 atm) in an appropriate apparatus. However, aqueous solutions usually deviate considerably from ideal behavior, and the deviations are greater the higher the concentrations. The quantitative relationships given above are exact only at infinite dilution.

Osmotic pressure

Owing to the constant thermal motion of all molecules in a fluid (above a temperature of absolute zero), solute species spread throughout the solution in a spontaneous tendency toward a state of equal concentration throughout. This migration of solutes in response to spatial differences in concentration is called diffusion that is a consequence of the second law of thermodynamics: matters move from high energy place to low energy place.

If a physical barrier is interposed between two regions, across the path of diffusion, and if that barrier is permeable to molecules of the solvent but not to those of the solute, the former will diffuse through the barrier in a process called osmosis (from the Greek $\omega\sigma\mu\sigma$, meaning 'push'). As in the case of unhindered diffusion, this process tends toward a state of uniform concentration even across the barrier. Barriers permeable to one substance in a solution but not to another are called selective or semipermeable membranes. Membranes surrounding cells in living organisms, for example, exhibit selective permeability to water while restricting the diffusion of solutes between the cells' interior and their exterior environment. Water molecules cross the membrane in both directions, but the net flow of water is from the more dilute solution to the more concentrated, following the second law of thermodynamics.

Fig. 7 is a schematic representation of a pure solvent separated from a solution by a semipermeable membrane. Solvent will pass through the membrane and enter the solution compartment, driving the solution level up the left-hand tube until the hydrostatic pressure of the column of dilute solution on the left is sufficient to counter the diffusion pressure of the solvent molecules drawn into the solution through the membrane. This process will cease when the chemical potentials of the solutions in both sides are equal or reach equilibrium. The hydrostatic pressure at equilibrium, when solvent molecules are crossing the membranes in both directions at equal rates, is the osmotic pressure of the solution.

In dilute solutions, the osmotic pressure is proportional to the concentration of the solution and to its temperature according to the following equation:

Fig. 7 Osmosis and osmotic pressure (Hillel, 1998): (a) in osmosis, the flow of water molecules through the membrane into the solutions is at first greater than the reverse flow from the solution into the water compartment due to a lower chemical potential in the solution compartment. The hydrostatic pressure due to the column of expanded solution increases the rate of water flow from the solution to the water compartment until, at equilibrium, the opposite flows are equal and the chemical potentials in both compartments are the same. (b) The osmotic pressure of the solution is equal to the hydrostatic pressure Π , which must be applied to the solution to equalize the rate of flow to and from the solution and produce a net flow of zero.

$$\Pi = MRT \quad (5)$$

Here Π is the osmotic pressure in atmospheres (to be multiplied by 0.101 to obtain megapascal units), M the total molar concentration of the solute (whether molecules or dissociated ions), T the temperature in degrees Kelvin, and R the gas constant (0.08205 liter atm deg.⁻¹ mole). The osmotic pressure increase with temperature is associated with the corresponding increase of the molecular diffusivity (self-diffusion coefficient) of water, D_w . According to the Einstein-Stokes equation,

$$D_w = kT/6\pi r\eta$$

where $k = R/N$, the Boltzmann constant (1.38×10^{-23} J K⁻¹); r is the rotation radius of the molecule ($\sim 1.5 \times 10^{-4}$) and η is the viscosity.

In soil, the concentration of solution is usually non-uniform near particle surface due to the formation of electrical double layer. Thereby, osmotic pressure in soil varies spatially near particle surface (Lu and Zhang, 2019). This phenomenon stems from the crystalline structure of clay minerals, where particle surfaces are usually negatively charged and balanced by counterions. This additional electrical field emanates from the particle surfaces, attracting cations, and repelling anions. The resulted cation concentration profile exhibits a maximum near the particle surface and decays to a constant value of the bulk solution concentration at the far field.

Solubility of gasses

The concentration of dissolved gasses in water in equilibrium with a gaseous phase generally increases with pressure and decreases with temperature. According to Henry's law, the mass concentration of a dissolved gas c_m is proportional to the partial pressure of the gas p_i :

$$c_m = s_o p_i / p_o \quad (7)$$

where s_o is the solubility coefficient of the particular gas in water and p_o is the total pressure of the atmosphere. The volume concentration is similarly proportional:

$$c_v = s_v p_i / p_o$$

where s_v is the solubility coefficient expressed in terms of volume ratios (i.e., c_v is the volume of dissolved gas relative to the volume of water). The values of s_o and s_v are determined experimentally. If the gas does not react chemically with the liquid, these properties should remain constant over a range of pressures, especially at low partial pressures of the dissolved gasses. Solubility is, however, strongly influenced by temperature. Table 2 gives the s_v values of several atmospheric gasses at various temperatures.

Vapor pressure

According to the kinetic theory, molecules in a liquid are in constant motion, which is an expression of their thermal energy. These molecules collide frequently, and occasionally one or another at the surface absorbs sufficient momentum to leap out of the liquid and into the atmosphere above it. Such a molecule, by virtue of its kinetic energy, thus changes from the liquid to the gaseous phase. This kinetic energy is then lost in overcoming the potential energy of intermolecular attraction while escaping from the liquid. At the same time, some of the randomly moving molecules in the gaseous phase may strike the surface of the liquid and be absorbed in it.

The relative rates of these two directions of movement depend upon the concentration of vapor in the atmosphere relative to its concentration at a state of equilibrium (i.e., when the movement in both directions is equal). An atmosphere that is at equilibrium with a body of pure water at standard atmospheric pressure is considered to be saturated with water vapor, and the partial pressure of the vapor in such an atmosphere is called the saturation (or equilibrium) vapor pressure. The vapor pressure at equilibrium with any body of water depends on the physical condition of the water (pressure and temperature) and its chemical condition (solutes) but is independent of the absolute or relative quantity of liquid or gas in the system.

Table 2 Solubility coefficients of gasses in water (Lu and Likos, 2004).

Temperature (°C)	Nitrogen (N ₂)	Oxygen (O ₂)	Carbon dioxide (CO ₂)	Air (without CO ₂)
0	0.0235	0.0489	1.713	0.0292
10	0.0186	0.0380	1.194	0.0228
20	0.0154	0.0310	0.878	0.0187
30	0.0134	0.0261	0.665	0.0156
40	0.0118	0.0231	0.530	0.0141

The solubilities of various gasses (particularly oxygen) in varying conditions strongly influence such vital soil processes as oxidation and reduction, and respiration by roots and microorganisms.

Table 3 Physical properties of water vapor (Hillel, 1998).

Temperature (°C)	Saturation vapor pressure (torr)		Vapor density in saturated air (kg m ⁻³)		Diffusion coefficient (m ² s ⁻¹) (× 10 ⁻⁴)
	Over liquid	Over ice	Over liquid (× 10 ⁻³)	Over ice (× 10 ⁻³)	
-10	2.15	1.95	2.36	2.14	0.211
-5	3.16	3.01	3.41	3.25	—

5	6.53	—	6.80	—	—
10	9.20	—	9.40	—	0.241
15	12.78	—	12.85	—	—
20	17.52	—	17.30	—	0.257
25	23.75	—	23.05	—	—
30	31.82	—	30.38	—	0.273
35	42.20	—	39.63	—	—
40	55.30	—	51.1	—	0.289
45	71.90	—	65.6	—	—
50	92.50	—	83.2	—	—

The saturation vapor pressure rises with temperature. As the kinetic energy of the molecules in the liquid increases, so does the evaporation rate. Consequently, a higher concentration of vapor in the atmosphere is required for the rate of return to the liquid to match the rate of escape from it. A liquid arrives at its boiling point when the vapor pressure becomes equal to the atmospheric pressure. If the temperature range is not too wide, the dependence of saturation vapor pressure on temperature is expressible by the equation (Table 3):

$$\ln p_o = a - b/T \quad (8)$$

where $\ln p_o$ is the logarithm to the base e of the saturation vapor pressure p_o , T is the absolute temperature, and a and b are constants.

As mentioned, the vapor pressure also depends on the hydrostatic pressure of the liquid water. At equilibrium with drops of water (which have a hydrostatic pressure greater than atmospheric), the vapor pressure is oversaturated and greater than in a state of equilibrium with free water (which has a flat interface with the atmosphere). On the other hand, in equilibrium with adsorbed or capillary water under a potential lower than free water, the vapor pressure is smaller than in equilibrium with free water. This phenomenon is called vapor pressure lowering. The curvature of water drops is considered to be positive, as these drops are convex toward the atmosphere, whereas the curvature of capillary water menisci is considered negative, as they are concave toward the atmosphere.

For water in capillaries, in which the air-water interface is concave, the Kelvin equation applies:

$$-(\mu_1 - \mu_1^o) = RT \ln (p_1^o/p_1) = 2\gamma v_1 \cos \alpha / r_c$$

in which $(\mu_1 - \mu_1^o)$ is the change in potential of the water due to the curvature of the air-water interface, γ is the surface tension of water, α is the contact angle, v_1 is the partial molar volume of water, and r_c is the radius of the capillary.

Water present in the soil invariably contains solutes, mainly electrolytic salts, in variable concentrations. Thus, soil water should properly be called the soil solution. The composition and concentration of the soil solution affect soil behavior. While in humid regions the soil solution may have a concentration of but a few parts per million, in arid regions the concentration may become as high as several percent. The ions commonly present are H^+ , Ca^{2+} , Mg^{2+} , Na^+ , K^+ , NH_4^+ , OH^- , Cl^- , HCO_3^- , NO_3^- , SO_4^{2-} , and CO_3^{2-} . The vapor pressure of electrolytic solutions is less than that of pure water. The equation is:

$$v_1 \Pi_o = RT \ln (p_1^o/p_1) = \mu_1 - \mu_1^o$$

wherein Π_o is the osmotic pressure of a nonvolatile solute, μ_1^o and p_1^o are the chemical potential and vapor pressure of the liquid in its pure state, and μ_1 and p_1 are the same for the solution. Thus, the soil solution has a lower vapor pressure than pure water, even when the soil is saturated. In unsaturated soil the capillary and adsorptive effects further lower the potential and hence also the vapor pressure.

Adsorption of water on soil surface and interlamellar

Adsorption is an interfacial phenomenon resulting from the differential forces of attraction or repulsion occurring among molecules or ions of different phases at their exposed surfaces. As a result of cohesive and adhesive forces coming into play, the zones of contact among phases may exhibit a concentration or a density of material different from and higher than that inside the phases themselves.

As different phases come in contact, various types of adsorption can occur: adsorption of gasses on solids, of gasses on liquid surfaces, and of liquids on solids.

The interfacial forces of attraction or repulsion may themselves be of different types, including electrostatic or ionic (Coulombic) forces, intermolecular forces such as van der Waals and London forces, and short-range repulsive (Born) forces. The adsorption of water upon solid surfaces is generally of an electrostatic nature. The polar water molecules attach to the charged faces of the solids and to the ions adsorbed on them. This adsorption of water is the mechanism causing the strong retention of water by clay at high suctions, resulting higher pore water pressure and density near soil particle surface and between clay interlamellar.

The interaction of the charges of the solid with the polar water molecules may impart to the adsorbed water a distinct structure in which the water dipoles assume an orientation dictated by the charge sites on the solids. The elevated pore water pressure in this adsorbed 'phase' could be as large as GPa in order of magnitude, and may induce abnormally elevated water density, highly suppressed fusion temperature, and significantly increased viscosity compared to ordinary liquid water at the same temperature. The adsorption of water on clay surfaces is an exothermic process, resulting in the liberation of an amount of heat known as the heat of wetting.

Surface tension

Surface tension is a phenomenon occurring typically, but not exclusively, at the interface of a liquid and a gas. The liquid behaves as if it were covered by an elastic membrane in a constant state of tension that tends to cause the surface to contract. To be sure, no such membrane exists but a thin layer with highly variable inter-water molecular stress, yet the analogy is a useful one if not taken too literally. If we draw an arbitrary line of length L on a liquid surface, there will be a force F pulling the surface to the right of the line and an equal force pulling the surface leftwards. The ratio F/L is the surface tension and its dimensions are those of force per unit length. The same phenomenon can also be described in terms of energy. Increasing the surface area of a liquid requires work, which remains stored as internal energy in the enlarged surface, just as energy can be stored in a stretched spring. That internal energy can perform work if the enlarged surface is allowed to contract again. Energy per unit area has the same dimensions as force per unit length.

An explanation for occurrence of surface tension is given in Fig. 8. A molecule inside the liquid is attracted in all directions equally by the cohesive forces of neighboring molecules, while a molecule at the surface of the liquid is attracted into the relatively dense liquid phase by a net force greater than that attracting it toward the rarified gaseous phase. This unbalanced force draws the surface molecules inward into the liquid and results in the tendency for the surface to contract. This is why drops of a liquid in air as well as bubbles of air in a liquid assume the shape of a sphere, which is a body of minimal surface exposure relative to its volume. The curvature of such sphere gives rise to a pressure difference across the liquid-air interface, viz. capillary pressure. A detailed explanation for this phenomenon can be found in the Chapter on Capillarity.

Different liquids exhibit different surface tension values with air, as in the following list at 20 °C:

Water, $7.27 \times 10^{-2} \text{ N m}^{-1}$ (72.7 dyn cm^{-1});
 Ethyl ether, $1.7 \times 10^{-2} \text{ N m}^{-1}$ (17 dyn cm^{-1});
 Ethyl alcohol, $2.2 \times 10^{-2} \text{ N m}^{-1}$ (22 dyn cm^{-1});
 Benzene, $2.9 \times 10^{-2} \text{ N m}^{-1}$ (29 dyn cm^{-1});
 Mercury, 0.43 N m^{-1} (430 dyn cm^{-1}).

Density and compressibility

Density of free water

The open packing of water molecules in ice and liquid water accounts for their relatively low densities. Unlike most substances, water exhibits a point of maximum density (at 4 °C), below which the substance expands due to the formation of a hexagonal lattice structure, and above which the expansion is due to the increasing thermal motion of the molecules. The coefficient of thermal

Fig. 8 Cohesive forces acting on a molecule inside the liquid and at its surface.

expansion of water is rather small, and in the normal temperature range of, say, 4–50 °C, the density diminishes only slightly, from 1000 to 988 kg m⁻³.

The compressibility of water, C_w , can be defined as the relative change in density with change in pressure:

$$C_w = (1/\rho_w)(d\rho_w/dP) \quad (9)$$

At 20 °C and at atmospheric pressure, the compressibility of pure water is about $4.6 \times 10^{-10} \text{ m}^2 \text{ N}^{-1}$. In the normal situations encountered on the surface of the Earth, water can usually be considered incompressible. The compression of water cannot be ignored, however, in the case of deep confined aquifers, which may be subject to a pressure of, say, 10 MPa or more.

Density of soil water

Water in soil can exhibit a density up to 1.872 g/cm³ (Zhang and Lu, 2018), depending on soil types mineral and water content (Fig. 9). Such a high-density value stems from the highly compressive pressure at the order of GPa near the particle surface induced by adsorption (Zhang and Lu, 2019). The magnitude of adsorption usually decays with the distance from particle surface or interlamellar surface (Lu and Zhang, 2019). Accordingly, the elevated soil water density decreases. As a result, the average water density in soil generally decays with water content because higher water content suggests more water lies further away from particle surface. The decay rate depends on the characteristics of adsorption strength of soil therefore varies with soil types, i.e., more prevalence in clayey soils with higher adsorption strength (Zhang and Lu, 2020).

Dynamic and kinematic viscosity

When a fluid is moved in shear (i.e., when adjacent layers of fluid are made to slide over each other), the force required is proportional to the velocity of shear. The proportionality factor is called the viscosity. As such, it is the property of the fluid to resist the rate of shearing and this can be visualized as an internal friction. The coefficient of viscosity η is defined as the force per unit area necessary to maintain a velocity difference of 1 m s⁻¹ between two parallel layers of fluid which are 1 m apart. The viscosity equation is:

$$\tau = \frac{F_s}{A} = \eta \, du/dx \quad (10)$$

wherein τ is the shearing stress, consisting of a force F_s acting on an area A ; η (dimensions: mass/(length × time)) is the coefficient of dynamic viscosity; and du/dx is the velocity gradient perpendicular to the stressed area A .

The ratio of the dynamic viscosity of a fluid to its density is called the kinematic viscosity, designated ν . It expresses the shearing-rate resistance of a fluid independently of the density. Thus, while the dynamic viscosity of water exceeds that of air by a factor of about 50 (at room temperature), its kinematic viscosity is actually lower.

Fluids of lower viscosity flow more readily and are said to possess greater fluidity (which is the reciprocal of viscosity). As shown in Table 4, the viscosity of water diminishes by over 2% per 1 °C rise in temperature, and thus decreases by more than half as the temperature increases from 5 °C to 35 °C. The viscosity is also affected by the type and concentration of solutes present.

Water is the origin of all the known forms of life. That is why the search for life usually begins with the search for water, e.g., the theme of NASA's Mars Exploration Program, "Seek Signs of life", begins with an exploration strategy known as "Follow the Water". Water occupies about half volume of cells and controls various biological processes by acting as a solvent, transporter, reactant, messenger, or catalyst (e.g., Brini et al., 2017). These indispensable roles come from water's unique polar molecular structure, for example, (1) the high polarity emanates electrostatic fields to attract other polar substances or ionic materials, facilitating the

Fig. 9 Water density in soils as a function of water content and soil types (Zhang and Lu, 2018).

dissolution and transportation of biomolecules, such as proteins and nucleic acids (e.g., Riveros-Perez and Riveros, 2018); (2) for non-polar molecules, the stronger hydrogen bonds among polar water molecules give rise to the hydrophobic effect, which is responsible for protein folding, formation of cell membranes, and adsorption of proteins into lipid layers (e.g., Ball, 2017; Riveros-Perez and Riveros, 2018); and (3) water molecule's polarity is the origin of surface tension and capillarity, which drives water rise in xylem of plants, and can be implemented in pharmacologic formulations and technologies (e.g., Brini et al., 2017; Riveros-Perez and Riveros, 2018). Additionally, water is the most common reactant for biological actions, e.g., cellular respiration and photosynthesis in plants. Summarizing, water involves in all the biochemical reactions directly or indirectly, and its unique properties play a vital role in sustaining the entire biosphere and living system.

Abstract

The concept of soil water potential is central to the characterization of water flow in unsaturated soils, to water retention, to plant available soil water and to soil strength. The concept is rooted in thermodynamic theory and reflects the attraction of soil and water, equilibrium between the liquid and vapor phases of soil water, and how gravity, pressure and soluble solutes affect soil water energy state and its exchanges with the atmosphere and plants. We review the historical roots of the water potential concept and offer practical definitions of the various components that contribute to water potential. Advances in measurement methods offer new insights into the relative influences of water potential components on water flow and exchanges with plants and the atmosphere.

Key points

- The historical origin of the soil water potential concept is reviewed.
- Various components that contribute to soil water potential are defined.
- Contemporary state-of-the-art measurement methods for all soil water potential components are presented.

Introduction

Water status in soils is characterized by both the amount of water present and its energy state. Soil water is subjected to forces of variable origin and intensity, thereby acquiring different quantities and forms of energy. The two primary forms of energy of interest here are kinetic and potential. Kinetic energy is acquired by virtue of motion and is proportional to velocity squared. However, because the movement of water in soils is relatively slow (usually less than 0.1 m h^{-1}), its kinetic energy is negligible. Potential energy, which is defined by the position of soil water within a soil body and by internal conditions, is largely responsible for determining soil water status under isothermal conditions. Like all other matter, soil water tends to move from where the potential energy is higher to where it is lower, in pursuit of equilibrium with its surroundings. The magnitude of the driving force behind such spontaneous motion is a difference in potential energy across a distance between two points of interest. At a macroscopic scale, we can define potential energy relative to a reference state. The standard state for soil water is defined as pure and free water (no solutes and no external forces other than gravity) at a reference pressure, temperature, and elevation, and is arbitrarily given the value of zero.

Historical perspective

Buckingham (1907) introduced the concept of *capillary potential* to quantify the energy state soil water as affected by the attraction between soil and water. In his 1907 monograph *Studies on the movement of soil moisture*, Buckingham wrote: “Then we may define ψ as the work required per centigram to pull water away from the mass of soil. We shall call ψ the capillary potential of the soil.” Buckingham’s definition of capillary potential has been formulated as a purely mechanical variable (no thermal effects) and for certain applications it remains an operational definition for the driving forces for flow in partially saturated porous media. We surmise that the reason that Buckingham did not pursue a more general definition of the water potential based on Gibbs thermodynamic

formalism was the complexity of gradients in capillary potential relative to gradients of linear transport laws such as Ohm's and Fourier's (for electric and temperature gradients). In reference to capillary flow, Buckingham wrote: "Furthermore, the other factor in the equation, namely, the gradient S , is not a simple and directly measurable quantity like a head of water, an electrical potential, or a temperature. It is a gradient of a quantity ψ , the attraction of the soil for water; and ψ depends in some as yet unknown way, differing from soil to soil, on water content of the soil, which can itself be measured only by tedious and not very accurate methods."

Buckingham had been exposed to Gibbs thermodynamic theory during his PhD studies in Leipzig (he graduated in 1893) under Wilhelm Ostwald. During that time, Ostwald translated Gibbs' work to German and lectured extensively on his interpretation of Gibbs' theory. After his graduation, Buckingham (1900) wrote a textbook on thermodynamics while teaching at Bryn Mawr College, a women's liberal arts college in Pennsylvania. In the preface to the book "An Outline of the Theory of Thermodynamics" that was published in 1900 Buckingham acknowledged the strong influence that Gibbs and Duhem, the French thermodynamicist, had on his writing. This solid background in thermodynamics and recognition of the importance of potential as a driving force for flow and attainment of equilibrium were the foundations for the pioneering work he later published during his tenure with the Bureau of Soils where he wrote his 1907 monograph and introduced the concept of potential to soil physics. Despite the limited scope of the mechanical potential for addressing capillary flows in soil, Buckingham added that "it is obvious that a rigorous treatment of the subject, with no restrictions imposed on either the water content or the soluble salt content of the soils, would have to use thermodynamic reasoning. But the simple conception of a mechanical potential will suffice for present purposes, though it is not impossible that with more comprehensive experimental data available we should have to use thermodynamic potential or the free energy."

It took nearly 4 decades for a more comprehensive theory of water potential to be developed using a broader thermodynamic basis. In their monograph on "The Thermodynamics of Soil Moisture" Edlefsen and Anderson (1943) applied Gibbs' approach to soil and plant physiology. They recognized the limitations of the mechanical potential (proposed by Buckingham) and wrote "Potential, for example, takes no explicit account of the effect of temperature on the total energy change of a system. Fortunately, another function, called 'free energy' was invented many years ago in the field of thermodynamics. This function combines all the criteria and characteristics of both potential and entropy that are most useful in the study of the thermodynamics of soil moisture and its use by plants."

Definition of soil water potential

Soil water is subject to several force fields, the combined effects of which result in a deviation in potential energy relative to the reference state, called the "total soil water potential" (ψ_T) defined as: "The amount of work that an infinitesimal unit quantity of water at equilibrium is capable of doing when it moves (isothermally and reversibly) to a pool of water at similar standard (reference) state, i.e., similar pressure, elevation, temperature and chemical composition."

A more formal definition of water potential requires the use of thermodynamic quantities such as Gibbs free energy G (or molar Gibbs free energy, g). The relations are based on the fundamental equation of internal energy (U) of an open system (i.e., mass of different substances can be exchanged reversibly with the surrounding while T and P vary mildly across the boundaries):

$$dU = TdS - PdV + \sum_{i=1}^j \frac{\partial U}{\partial n_i} dn_i \quad (1)$$

where T is the temperature (K), S the entropy ($J K^{-1}$), P the pressure (Pa) and V is the volume (m^3). The last term is a summation over changes in the amounts of substances, each representing the contribution to the chemical potential μ ($J mol^{-1}$) of the system:

$$\mu_i = \left(\frac{\partial U}{\partial n_i} \right)_{S,V,n} \quad (2)$$

The Gibbs free energy is defined as: $G = U + PV - TS$, and it offers certain advantages over the use of the internal energy (U) for soil water applications. Taking the total differential dG and replacing dU with Eq. (1) yields:

$$dG = VdP - SdT + \sum_{i=1}^j \mu_i dn_i \quad (3)$$

We can normalize the Gibbs free energy, entropy, and volume (the extensive variables) per mol, i.e., g ($J mol^{-1}$), S ($J mol^{-1} K^{-1}$), V ($m^3 mol^{-1}$) to find for a single pure substance (water) that: $d\mu = dg = VdP - SdT$ (Bejan, 1997). In other words, the molar Gibbs free energy is equal to the chemical potential. The foregoing analysis is not meant to offer a rigorous thermodynamic derivation of water potential in soil but to provide a few thermodynamic links with definitions below.

Based on thermodynamic terms, a formal definition of water potential ψ ($J m^{-3}$) that parallels the verbal definition above is given as (Slatyer and Taylor, 1960):

$$\psi = \frac{(\mu_w - \mu_{w,0})}{\bar{v}_{w,0}} \quad (4)$$

with μ_w ($J mol^{-1}$) the chemical potential of water in a soil sample, $\mu_{w,0}$ ($J mol^{-1}$) the chemical potential for pure water at reference state (originally referred to the same temperature as the sample) where the definition is extended to a similar

reference state (temperature, elevation, pressure, and chemical composition). Similarly, the partial molar volume at reference state $\bar{v}_{w,0}$ ($\sim 18 \times 10^{-6} \text{ m}^3 \text{ mol}^{-1} \sim 0.001 \text{ m}^3 \text{ kg}^{-1}$) converts the molar units (J mol^{-1}) to J m^{-3} or units of pressure (Pa).

Components of the water potential

The primary forces acting on soil water held within a rigid soil matrix under isothermal conditions can be conveniently grouped as: (1) matric forces resulting from interactions of the solid phase with the liquid and gaseous phases; (2) osmotic forces owing to differences in chemical composition of the soil solution; and (3) body forces induced by gravitational and other inertial force fields (e.g., centrifugal). The thermodynamic approach, whereby potential energy rather than forces is used, is particularly useful for equilibrium and flow considerations. Equilibrium would require the vector sum of these different forces acting on a body of water in different directions to be zero—this is an extremely difficult criterion to deal with in soils. On the other hand, potential energy, mathematically defined as the negative integral of the force over the path taken by an infinitesimal amount of water when it moves from a reference location to the point under consideration, is a scalar and not a vector. Subsequently, we can express the total potential as the algebraic sum of the component potentials corresponding to the different fields acting on soil water:

$$\Psi_T = \Psi_m + \Psi_s + \Psi_p + \Psi_z \quad (5)$$

where the component potentials ψ_i are discussed below.

ψ_m is the matric potential resulting from the combined effects of capillarity and adsorptive forces within the soil matrix. The primary mechanisms for these effects include: (1) capillarity caused by liquid-gas interfaces forming and interacting within the irregular soil-pore geometry; (2) adhesion of water molecules to solid surfaces due to short-range London-van der Waals forces and extension of these effects by cohesion through hydrogen bonds formed in the liquid; and (3) ion hydration and water participating in diffuse double layers—particularly near clay surfaces. There is some disagreement regarding the practical definition of this component of the total potential. Some consider all contributions other than gravity and solute interactions at a reference atmospheric pressure. Others use a tensiometer to measure and provide a practical definition of the matric potential in a soil volume of interest that is in contact with a tensiometer's porous cup. The value of ψ_m ranges from zero when the soil is saturated to increasingly negative values as the soil becomes drier (note that $\psi_m = 0 \text{ mm}$ is greater than $\psi_m = -1000 \text{ mm}$; in analogy, a temperature of 0°C is greater than -10°C).

The representation of flow and transport in unsaturated soils, particularly at low water contents, commonly lumps capillary and adsorptive forces without distinguishing their individual contributions to the matric potential (Tuller et al., 1999). However, as emphasized by Nitao and Bear (1996), the distinctive consideration of adsorptive surface forces and liquid films is essential for advanced flow and transport theories. Hence, we seek to expand the “capillary-centered” standard treatment by incorporating the contribution of adsorptive forces to the matric potential component of soil water. Following Philip (1977), we thus express the liquid-vapor interface as a surface of constant, partial specific Gibbs free-energy (or matric potential) made up of an adsorptive component (A) and a capillary component (C) (more rigorous representations of these contributions are found in Radke (2015) and Kaptay (2018)):

$$\Psi_m = A(h) + C(\kappa) \quad (6)$$

with κ as the mean curvature of the liquid-vapor interface, and h as the distance from the solid to the liquid-vapor interface taken normal to the solid surface (i.e., thickness of the adsorbed film). The capillary component C is given by the classic Young–Laplace equation:

$$C(\kappa) = \frac{-2\sigma\kappa}{\rho} \quad (7)$$

where κ is positive for an interface concave outward from the liquid, σ is the surface tension at the interface, and ρ is the density of the liquid.

The adsorptive component in Eq. (6) is attributed to two types of surface forces (Derjaguin et al., 1987). The first kind includes longer-range ($>500 \text{ \AA}$) electrostatic forces (e.g., diffuse double layer, DDL), and shorter-range ($<100 \text{ \AA}$) van der Waals and hydration forces, responsible for molecular interactions and structural changes in water molecules near the solid surface. The second kind of surface forces is comprised of longer-range forces due to the overlapping of two interfacial regions (e.g., mutual attraction between two clay platelets across a slit-shaped pore space). The combined effect of such interfacial interactions results in a difference in chemical potentials between the liquid in the adsorbed film and the bulk liquid phase. This difference in chemical potentials may be expressed as an equivalent interfacial force per unit area of the interface, termed the “disjoining pressure” (Π). The disjoining pressure is a function of liquid film thickness (h), and it can also be viewed as the difference between a normal component of liquid film pressure, P_N (in equilibrium with the gaseous phase $P_N = P_G$), and the pressure in the bulk liquid phase, P_L :

$$\Pi(h) = P_N(h) - P_L = P_G - P_L \quad (8)$$

The disjoining pressure is related to more conventional thermodynamic quantities such as Gibbs free energy. Gibbs free energy (G) per unit area of the interface may be defined on the basis of $\Pi(h)$ isotherms for constant pressure P_L , temperature T , and chemical (μ) and electric potentials of the liquid-gaseous and the liquid–solid interfaces as:

$$G(h) = - \int_{\infty}^h \Pi(h) dh \quad (9)$$

The value of $G(h)$ is equal to the work of thinning the film in a reversible isobaric-isothermal process from ∞ to a finite thickness h , with $\Pi(h) = -(\partial G/\partial h)_{T, P_L, \mu, \psi_g, \psi_s}$. The use of $\Pi(h)$ as the basic thermodynamic property is not a mere change of notation, as $\Pi(h)$ has advantages in cases where Gibbs thermodynamic theory is difficult to define, such as when interfacial zones overlap to the extent that the film does not retain the intensive properties of the bulk phase. The use of the disjoining pressure is advantageous from an experimental point of view because of the relative ease in accounting for different contributions (e.g., electrostatic effects).

The disjoining pressure is a sum of several components, similar to the concept of total soil water potential discussed above. The primary components of $\Pi(h)$ in porous media are molecular, $\Pi_m(h)$, electrostatic, $\Pi_e(h)$, structural, $\Pi_s(h)$, and adsorptive $\Pi_a(h)$:

$$\Pi(h) = \Pi_m(h) + \Pi_e(h) + \Pi_s(h) + \Pi_a(h) \quad (10)$$

$\Pi_m(h)$: The molecular component originates from van der Waals interaction between macro-objects (e.g., parallel clay plates). Various expressions, with $\Pi_m(h)$ often proportional to h^{-3} , were derived by [Paunov et al. \(1996\)](#) and [Iwamatsu and Horii \(1996\)](#).

$\Pi_e(h)$: The electrostatic component of the disjoining pressure is calculated from the solution of the Poisson-Boltzmann equation for the DDL with appropriate boundary conditions. Approximate solutions are adequate for many applications, often with $\Pi_e(h) \propto h^{-2}$.

$\Pi_s(h)$: Some controversy exists regarding the origin of the structural component; some attribute it to changes in the structure (density) of water adjacent to solid surfaces and deformation of hydrated shells, while others attribute this force to the presence of a layer with a lower dielectric constant near the surface. Regardless of its exact origin, this component is responsible for the so-called hydration repulsion which stabilizes dispersion and prevents coagulation of some colloidal particles, even at high electrolyte concentrations: $\Pi_s(h) \propto h^{-1}$.

$\Pi_a(h)$: The adsorptive component of the disjoining pressure results from nonuniform concentrations in the water film due to unequal interaction energies of solute and solvent with interfaces in nonionic solutions. This is different than the nonuniform distribution of charged ions. This component of the disjoining pressure is likely to become very important for interactions between nonpolar molecules (e.g., NAPLs) which give rise to repulsive forces in the liquid film.

The form of the disjoining pressure isotherm $\Pi(h)$ is determined by the nature of surface forces. While the molecular component $\Pi_m(h)$ is always present, the influence of other components depends on surface properties, liquid polarity and its composition, and adsorption of dissolved components. The range of the electrostatic forces in dilute solutions of a 1:1 electrolyte (10^{-6} – 10^{-7} mol L⁻¹) is in the range of 0.3–1.0 μ m. Consequently, relatively thick films of water and aqueous electrolyte solutions ($h > 50$ nm) are stable mainly through the $\Pi_e(h)$ component of disjoining pressure. The magnitude and contribution of $\Pi_e(h)$ primarily depend on the charges of the film and substrate surfaces. Dispersion forces become appreciable in the range $h < 50$ nm, and their influence is enhanced by large differences between the permittivity of the liquid and the solid. The forces of structural repulsion may come to play when the film thickness is less than 10 nm.

ψ_s is the solute or osmotic potential determined by the presence of solutes in soil water, which lower its potential energy and its vapor pressure. The effects of ψ_s are important when: (1) there are appreciable amounts of solutes in the soil; and (2) in the presence of a selectively permeable membrane or a diffusion barrier which transmits water more readily than salts. The effects of ψ_s are otherwise generally negligible when only liquid water flow is considered, and no diffusion barrier exists. The two most important diffusion barriers in the soil are: (1) soil-plant root interfaces (cell membranes are selectively permeable); and (2) air–water interfaces, thus, when water evaporates, salts are left behind. In dilute solutions the solute potential, also called the osmotic pressure, is proportional to the concentration and temperature according to:

$$\Psi_s = -RTC_s \quad (11)$$

where ψ_s is in kPa, R is the universal gas constant (0.008314 kPa m³mol⁻¹K⁻¹), T is absolute temperature (K), and C_s is solute concentration (mol m⁻³). A useful approximation which may be used to estimate ψ_s in kPa from the electrical conductivity of the soil solution at saturation (EC_s) in deciSiemens per meter (dS m⁻¹) is:

$$\Psi_s \approx -36EC_s \quad (12)$$

ψ_p is the pressure potential, defined as the hydrostatic pressure exerted by unsupported water saturating the soil above a point of interest. Using units of energy per unit weight provides a simple and practical definition of ψ_p as the vertical distance from the point of interest to the free water surface (unconfined water table elevation). The convention used here is that ψ_p is always positive below a water table, or zero if the point of interest is at or above the water table. In this sense, nonzero magnitudes of ψ_p and ψ_m are mutually exclusive: either ψ_p is positive and ψ_m is zero (saturated conditions), or ψ_m is negative and ψ_p is zero (unsaturated conditions), or $\psi_p = \psi_m = 0$ at the free water table elevation. Note that some prefer to combine the pressure and matric components into a single term, which assumes positive values under saturated conditions and negative values under unsaturated conditions. Based on operational and explanatory considerations, we prefer to adopt the more commonly used separate components protocol.

ψ_z is the **gravitational potential**, which is determined solely by the elevation of a point relative to an arbitrary reference point and is equal to the work needed to raise a body against the Earth's gravitational pull from a reference level to its present position. When expressed as energy per unit weight, the gravitational potential is simply the vertical distance from a reference level to the point of interest. The numerical value of ψ_z itself is thus not important (it is defined with respect to an arbitrary reference level)—what is important is the difference (or gradient) in ψ_z between any two points of interest. This value is invariant of the reference level location.

Soil water is at equilibrium when the net force on an infinitesimal body of water equals zero everywhere, or when the total potential is constant in the system. Though the last statement is a logical consequence of the definitions above, it is not strictly true. Constant total potential is a necessary but not a sufficient condition, and, for thermodynamic equilibrium to prevail, three conditions must be met simultaneously: (1) thermal equilibrium, or uniform temperature; (2) mechanical equilibrium, meaning no net convection-producing force; and (3) chemical equilibrium, meaning no net diffusional transport or chemical reaction. In most practical applications, however, the macroscopic definition of the total potential and equilibrium conditions based on it are completely adequate.

The difference in chemical and mechanical potentials between soil water and pure water at the same temperature is known as the soil water potential ψ_w :

$$\Psi_w = \Psi_m + \Psi_s + \Psi_p \quad (13)$$

Note that the gravitational component (ψ_z) is absent in this definition. Soil water potential is thus the result of inherent properties of soil water itself, and of its physical and chemical interactions with its surroundings, whereas the total potential ψ_T includes the effects of gravity (an “external” and ubiquitous force field).

Total soil water potential and its components may be expressed in several ways depending on the definition of a “unit quantity of water.” Potential may be expressed as (1) energy per unit of mass; (2) energy per unit of volume; or (3) energy per unit of weight. A summary of the resulting dimensions, common symbols, and units are presented in Table 1.

Only μ has actual units of potential; ψ has units of pressure, and h of head of water. However, the above terminology (i.e., potential energy expressions rather than units of potential per se) is widely used in a generic sense in the soil and plant sciences. The various expressions of soil water energy status are equivalent, with:

$$\mu = \frac{\Psi}{\rho_w} = gh \quad (14)$$

where ρ_w is density of water (1000 kg m^{-3} at 20°C) and g is gravitational acceleration (9.81 m s^{-2}).

Measurement of soil water potential components

Total water potential

Psychrometric methods are commonly used for the measurement of the water potential (ψ_w) in soils (also in plants and food). The potential of the soil solution is in thermodynamic equilibrium with its ambient water vapor. Taking the vapor pressure above pure water at reference state ($\psi_w = 0$) as e_0 , the vapor pressure (e) over a salt solution or water held in soil pores by matric forces is depressed relative to the reference state, i.e., $e < e_0$. A convenient measure obtained by the psychrometer is the relative vapor pressure of the ambient soil atmosphere, which is related to the water potential (ψ_w) of soil water through the well-known Kelvin equation:

$$RH = \frac{e}{e_0} = e^{\left(\frac{M_w \psi_w}{\rho_w RT}\right)} \quad (15)$$

where e is water vapor pressure (kPa), e_0 is saturated vapor pressure at the same temperature, M_w is the molecular weight of water ($0.018 \text{ kg mol}^{-1}$), R is the ideal gas constant ($8.31 \text{ J K}^{-1} \text{ mol}^{-1}$ or $0.008314 \text{ kPa m}^3 \text{ mol}^{-1} \text{ K}^{-1}$), T is absolute temperature (Kelvin), and ρ_w is the density of water (kg m^{-3}). Rearranging and taking a log-transformation of Eq. (15) yields an expression for water potential ψ_w :

$$\Psi_w = \frac{RT\rho_w}{M_w} \ln \left(\frac{e}{e_0} \right) \quad (16)$$

Table 1 Expressions for the total soil water potential and its components.

Units	Symbol	Name	Dimensions	SI units	CGS units
Energy/mass	μ	Chemical potential	$L^2 t^{-2}$	J kg^{-1}	erg g^{-1}
Energy/volume	ψ	Soil water potential, suction, or tension	$ML^{-1} t^{-2}$	Nm^{-2} (Pa)	erg cm^{-3}
Energy/weight	h	Pressure head	L	m	cm

L , length, M , mass; t , time

Fig. 1 (A) A WP4C laboratory psychrometer (METER Group, Pullman, WA, USA). (B) Sample chamber of the WP4C psychrometer.

The water potential in drier soils is lower, such that fewer water molecules “escape” into the ambient atmosphere, resulting in lower relative humidity (lower relative vapor pressure). Concentrated soil solutions having lower osmotic potentials have similar effect on reducing vapor pressure, as more water molecules are associated with hydrated salt molecules and are less free to “escape” the liquid state. The inability to distinguish between matric and osmotic effects limits psychrometric measurements to soil water potential only. In some cases where the osmotic potential is negligible, psychrometric measurements are used to infer the matric potential.

Fig. 1A depicts a WP4C laboratory psychrometer (METER Group, Pullman, WA, USA). The stainless steel cup that contains the soil sample is sealed against a sensor block (Fig. 1B). The soil sample equilibrates with the vapor in the headspace. A fan controls the boundary layer conductance of the dew point mirror and shortens equilibration time. An infrared (IR) thermometer measures the sample temperature, and a dew point mirror measures the dew point temperature of the air in the headspace, which allows calculation of the vapor pressure of the air in the headspace as the saturation vapor pressure at dew point temperature. When the water potential of the sample and the headspace air are in equilibrium, the measurement of the headspace vapor pressure and sample temperature (from which saturation vapor pressure is calculated) gives the water potential of the sample according to Eq. (16).

Temperature plays a crucial role for accurate ψ_w measurements. Most critical is the measurement of the difference between sample and dew point temperature. To achieve a ψ_w measurement resolution of 0.05 MPa, temperature differences need to be measured at a resolution of 0.006 °C.

Psychrometers measure the combined matric (ψ_m) and solute (ψ_s) potentials. The solute potential can be approximated based on the electrical conductivity (EC) of the soil solution (Eq. (12)). The matric potential may be calculated by subtracting ψ_s from ψ_w . The measurement range of the WP4C Dewpoint PotentiaMeter is from –100 to –300,000 kPa.

Pressure potential

Piezometers are commonly applied to measure ψ_p . A piezometer (Fig. 2A) is a tube that is inserted into the soil to depths below the water table and that extends to the soil surface and is open to the atmosphere. The bottom of the piezometer is perforated to allow soil water under positive hydrostatic pressure to enter the tube. Water enters the tube and rises to a height equal to that of the unconfined water table. The elevation of the free water table is measured relative to the soil surface using a steel tape with a water level sounder or other electro-optic devices that indicate when the tip of the steel tape touches the water table. The value of pressure potential expressed as energy per weight is simply the vertical distance from a point of interest to the surface of the free water table. Pressure potentials above the water table surface are always zero (nonzero pressure and matric potentials are mutually exclusive). For automated continuous water level measurements modern loggers that rely on pressure transducers for the measurement of the hydrostatic and barometric pressures are commonly employed (Fig. 2B).

Matric potential

Tensiometers or heat-dissipation sensors are commonly applied to measure soil matric potential. A tensiometer consists of a porous cup, usually made of ceramic and having very fine pores, connected to a vacuum gauge through a water-filled tube (Fig. 3). The porous cup is placed in intimate contact with the bulk soil at the depth of measurement. When the matric potential of the soil is lower (more negative) than inside the tensiometer, water moves from the tensiometer along a potential energy gradient to the soil through the saturated porous cup, thereby creating suction sensed by the gauge. Water flow into the soil continues until equilibrium is reached and the suction inside the tensiometer equals the soil matric potential. When the soil is wetted, flow may occur in the reverse direction, i.e., soil water enters the tensiometer until a new equilibrium is attained. The tensiometer equation is given as:

$$\Psi_m = \Psi_{gauge} + (z_{gauge} - z_{cup}) \quad (17)$$

with ψ_{gauge} the reading at the vacuum gauge location and z indicating depth. The vertical distance from the gauge plane to the cup, expressed as a negative quantity when the cup is lower than the gauge as is usually the case, must be added to the matric potential

Fig. 2 (A) The concept of piezometer measurements. (B) HOB0[®] MX2001 water level logger (Copyright 1996–2012 Onset Computer Corporation, 470 MacArthur Blvd, Bourne, MA 02532 U.S.A., all rights reserved).

Fig. 3 Tensiometers for matric potential measurement using vacuum gauges and electronic pressure transducers.

measured by the gauge (ψ_{gauge}) in order to obtain the matric potential at the depth of the cup. This accounts for the positive head exerted by the overlying tensiometer water column at the depth of the ceramic cup. Note that using the difference in vertical elevation is appropriate only when potentials are expressed per unit of weight. Electronic sensors called pressure transducers often replace mechanical vacuum gauges. The transducers convert mechanical pressure into an electric signal which can be more easily and more precisely measured. In practice, pressure transducers can provide more accurate readings than other gauges, and in combination with data-logging equipment are able to supply continuous measurements of matric potential.

The tensiometer range is limited to suctions (absolute values of the matric potential) of less than 100 kPa, i.e., 1 bar, 10 m head of water, or 1 atm. This is because the air entry value of the porous cup is equivalent to 100 kPa. Therefore, other means are needed for matric potential measurement under drier conditions.

Heat-dissipation sensors may be applied for a matric potential range from -1 to -1000 MPa. The rate of heat dissipation in a porous medium is dependent on the medium's specific heat capacity, thermal conductivity, and density. The heat capacity and thermal conductivity of a porous matrix are affected by its water content. Heat dissipation sensors contain heating elements in line-

Fig. 4 (A) 229 heat dissipation matrix potential sensor (Campbell Scientific, Inc., Logan, UT, USA). (B) Tensiomark heat dissipation matrix potential sensor (ecoTech Umwelt-Meßsysteme GmbH, Bonn, Germany).

Fig. 5 TEROS 21 Water Potential Sensor (METER Group, Pullman, WA, USA).

or point-source configurations embedded in a rigid porous matrix with fixed pore space. The measurement is based on application of a heat pulse by applying a constant current through the heating element for specified time period, and analysis of the temperature response measured by a thermocouple placed at a fixed distance from the heating source. With the heat dissipation sensor buried in the soil, changes in soil water matric potential result in a gradient between the soil and the porous ceramic matrix, inducing water flow between the two materials until a new equilibrium is established. The water flow changes the water content of the ceramic matrix which, in turn, changes the thermal conductivity and heat capacity of the sensor, and hence the measured temperature response to the applied heat pulse.

Fig. 4A depicts the 229 heat dissipation matrix potential sensor (Campbell Scientific, Inc., Logan, UT, USA) that consists of a heating element and thermocouple placed in epoxy in a hypodermic needle, which is encased in a porous ceramic matrix. The sensor's measurement range is from -10 to -2500 kPa. It requires soil specific calibration and an excitation current of 50 mA. A Tensiomark heat dissipation sensor (ecoTech Umwelt-Meßsysteme GmbH, Bonn, Germany) with a measurement range from -1 to -1000 MPa is shown in Fig. 4B.

Additional means for in-situ measurements of ψ_m , are sensors such as the TEROS 21 (METER Group, Pullman, WA, USA) (Fig. 5). This sensor consists of a capacitance soil moisture sensor that is sandwiched between porous ceramic disks with known water characteristic. Metal screens attached to the ceramic disks prevent fringing of the electromagnetic field into the surrounding soil. The ceramic disks are brought in close hydraulic contact with the surrounding soil, which allows the ψ_m of the soil and porous ceramic substrate to equilibrate. The ψ_m is inferred from the measured volumetric water content of the ceramic substrate and its known water characteristic. The measurement range of the TEROS 21 sensor is from -5 to $-100,000$ kPa.

Osmotic potential

Soil water solutions contain varied quantities and compositions of dissolved salts. The relationships between the salt concentration and ψ_s , and the possibility for estimating ψ_s from the electrical conductivity (EC) of the soil solution, were discussed above. Conventional measurement of soil solution EC involves solution extraction from saturated soil samples and measuring the EC using an electrical conductivity meter (Fig. 6A).

Fig. 6 (A) Handheld electrical conductivity (EC) meter; (B) Time domain reflectometry (TDR) probes and solution EC vs concentration measured with TDR and EC meter. Reproduced from Mmolawa, K.B. and Or, D. (2000) Root zone solute dynamics under drip irrigation: a review. *Plant and Soil* 222: 163–190.

Electrical conductivity meters rely on Ohm's law:

$$E = I R \quad (18)$$

with E the electromotive force (volts), I the current flow (amperes), and R the resistance (ohms). For constant voltage, the current flowing through the solution is inversely proportional to the electrical resistance, or directly proportional to the electrical conductance. The solution EC is thus determined from known voltage and electrode geometry and measurement of the electric current. More recently, a variety of in situ methods, such as time-domain reflectometry (TDR), have been used to deduce soil bulk EC from electromagnetic signal attenuation (Mmolawa and Or, 2000), hence enabling simultaneous measurements of water content and soil EC in the same undisturbed soil volume (Fig. 6B). Concurrent knowledge of θ and EC can be used to infer the soil solution EC, and hence to estimate ψ_s .

Summary

The soil water potential framework is central to the quantification of the energy state of soil water and features prominently in the driving forces for water and vapor flow in soil. Soil water potential is also important for exchanges with the atmosphere and for soil-plant interactions including plant response to changes in water availability (a similar concept applies to flow and transport within plants). We provided a historical context for the origins of the soil water potential and presented the various components that contribute to soil water potential. We reviewed and discussed contemporary measurement methods used for soil water potential determination in laboratory and field conditions.

Abstract

In this article, I briefly review techniques for measuring the soil water content and soil water potential. Whereas a large number of methods have been developed to measure these properties in the past, only a few techniques are of interest nowadays, are commercially available, and used as standard sensors. Water content is nowadays primarily measured with sensors that measure the electric permittivity of soils. For soil water potential, no single technique is suited to cover the whole range of suctions. Depending on the wetness, tensiometers, equivalent porous media sensors, or psychrometric methods are suited.

Key points

- The water content and matric potential of the soil are measured in situ by placing electronic sensors in the soil.
- Today, the measurement of water content in natural soils is mostly based on the measurement of permittivity.
- Water content measurements using sensors embedded in the soil are highly influenced by local variability of soil properties and sensor placement conditions. Furthermore, they encompass only small sample volumes.
- Matric potentials in soils can be determined very accurately under wet conditions using tensiometers, but these instruments fail under dry conditions.
- Commercially available matric potential sensors for the medium moisture range are based on the principle of equilibrating an equivalent porous medium. In practice such sensors cover water potential ranges between -10 and -5000 kPa. They are widely available, but have rarely been tested against each other under real field conditions.
- Measurement of total water potential under dry conditions is possible but rarely applied in the field. It can be measured using psychrometric techniques, but the instruments are affected considerably by temperature conditions.
- The link between large-scale soil moisture monitoring, e.g., by cosmic ray probes or satellite microwave monitoring and local soil moisture monitoring is an ongoing research topic.

Nomenclature

Gravimetric water content w [kg kg ⁻¹]	Mass of water per mass of dry soil.
Gravitational potential ψ_g [kPa]	Energy per volume of water caused by an elevation difference to a reference plain. Positive above the reference plain, negative below it.
Hydraulic potential Φ [kPa]	Sum of matric and gravitational potential, i.e., $\Phi = \psi_m + \psi_g$ resp. $H = h_m + h_g$.
Hydrostatic potential ψ_h [kPa]	Energy per volume of water exerted by positive fluid pressure due to a surcharge of water at water saturation, positive.
Matric potential ψ_m [kPa]	Energy per volume of water exerted on the water phase by capillary forces and water-solid interactions, negative in unsaturated soils.
Osmotic potential ψ_o [kPa]	Energy per volume of water caused by the presence of solutes in the water phase, always negative.
pF	Logarithmic unit for suction, defined as $\text{pF} = \log_{10}(h \text{ [cm]})$.
Pressure head h [m]	Energy per weight of water. All water potential components can be expressed in units of pressure heads.
Suction	Absolute value of the matric potential, either in units of pressure [kPa] or in units of pressure head [m]
Tension	Synonym to suction.
Total potential ψ_t or h_t	Sum of all potential components, i.e., $\psi_t = \psi_m + \psi_g + \psi_o + \psi_h$ in pressure units, of $h_t = h_m + h_g + h_o + h_h$ in units of pressure head.
Volumetric water content θ [m ³ m ⁻³]	Volume of water per volume of soil.

Introduction

Soil moisture influences the exchange of energy, water, solutes, and carbon within the soil-vegetation-atmosphere system (e.g., Vereecken et al., 2008). Two variables define soil moisture, namely water content and water potential. Both, soil water content and soil water potential, fundamentally affect a wide variety of biophysical processes, such as seed germination, plant nutrition, and plant wilting. Soil water content controls to a great extent soil mechanical, thermal, chemical and biological properties. Soil water potential, in contrast, is the key variable that determines dissipative water movement in soil and the availability of water to plants. Hydrological processes, such as infiltration, redistribution, evaporation, transpiration, deep percolation and groundwater renewal, are caused by gradients in soil water potential (Bittelli, 2010). Knowledge of the relationship between water content and matric potential, which is the most important component of the total water potential in unsaturated soils, is required to model the soil water balance. Such modeling provides an indispensable tool for many applications in agricultural and horticultural management, such as managing irrigation, minimizing fertilizer use and loss, and optimizing agricultural production. It is also key for assessing contaminant transport in soil and water exchange between the soil-atmosphere interface, which relates to weather forecast and local climate. In this article, we briefly review techniques for measuring the soil water content and soil water potential. Although a large number of experimental methods have been developed to measure these quantities over the last century, there are now only a few techniques that are used widely, commercially available and used as standard sensors.

Terminology and units of soil water content and soil water potential

Soil water content is a measure of the amount of water (volume or mass) contained in a unit volume or mass of soil. If the measure is the volume of water per unit volume of soil, the water content is called the ‘volume wetness’ or ‘volumetric water content’, θ [m³ m⁻³]. If it is the mass of water per unit mass of dry soil it is called the ‘mass wetness’ or ‘gravimetric water content’, w [kg kg⁻¹]. The gravimetric water content is given by the mass of water per unit mass of dry soil. The two water content measures are related by:

$$\theta = \frac{\rho_b}{\rho_w} w \quad (1)$$

where ρ_b [kg m⁻³] is the bulk density of the soil (mass of dry soil per unit volume) and ρ_w [kg m⁻³] is the density of water ($\approx 10^3$ kg m⁻³). The volumetric water content can range from 0 to a maximum value that is equal to the porosity of a soil. In typical soils, porosity is between 0.35 and 0.7, but in specific media (e.g. peat) the porosity can reach values of >95% and accordingly volumetric water contents also can be this large. Very often, water contents are listed without units (volume per volume or mass per mass cancel each other out) and are expressed as percent (θ in the range 0 ... 100%). However, this is poor practice and expressing units minimizes interpretation errors.

Soil water potential reflects the energy state of water in porous media and incorporates capillarity, adsorption, gravity, osmosis and positive pressure under saturated conditions. This energy state is given relative to water in a standard state, in which it is free of solutes, free from external forces except gravity, and at a reference pressure, reference temperature and reference elevation. In particular, it is free from any forces that can be exerted to the water phase by nearness to the soil matrix, such as solid-liquid interphase forces (capillary forces). These forces provide a key component of soil water potential, and are summarized as matric potential, ψ_m (Luo et al., 2022). The elevation of a water-filled point in soil with respect to a reference elevation (often the soil surface) determines the gravitational potential (ψ_g). Presence of solutes in the soil solution decreases the potential energy of water with respect to solute free water and is expressed as osmotic potential (ψ_o). Under saturated conditions, water overlying over a point of interest exerts a pressure, which is termed soil hydrostatic potential (ψ_h) (also called pressure potential). When quantifying the water potential, at least these components have to be taken into account, and the total water potential ψ_t is thus given by

$$\psi_t = \psi_m + \psi_g + \psi_o + \psi_h \quad (2)$$

Note that in Eq. (2) only ψ_m or ψ_h can be different from zero, since under water-saturated conditions ψ_m is zero by definition, and in unsaturated conditions there is no pressure from overlying water, i.e., $\psi_h = 0$. Thus, ψ_h is a positive pressure component compared with the matric potential, which is negative. Other forces that act on the water in a porous medium and contribute to total potential are the air pressure in pores, expressed as pneumatic potential, and the force that acts on water in the case of a load of an unconsolidated matrix, which is termed overburden potential. However, the latter two pressures do not prevail in typical soils, since air pressure is assumed to be equal in a continuous air phase, and particle load is in most soils held by particle-particle contacts. Thus, they can normally be neglected. Finally, the osmotic pressure is in most cases neglected and assumed to show significant gradients in soils only in the case of strong salt content gradients, which rarely occurs under humid climates. However, when considering water uptake by plant roots in drying soils, the osmotic component may become important. In any situation, the matric potential and the gravitational potential must be taken into account. These two components are combined to form the 'hydraulic potential' which is a key variable in any simulation of water transport in unsaturated porous media.

To quantify the energy state of soil water, it must be related to an amount of water. It can be expressed as energy per mass of water (J kg^{-1}), as energy per volume of water (J m^{-3}), which is equivalent to pressure (Pa), or as energy per unit weight of water ($\text{J (9810 kg m s}^{-2})^{-1}$). The latter unit appears not straightforward on first sight, but since $1 \text{ J} = 1 \text{ kg m}^2 \text{ s}^{-2}$, it leads to the expression of the water potential as *pressure head*, in units of water column length (m or cm). This is convenient, and thus it is commonly used in soil physics and vadose zone hydrology (Durner and Or, 2005). The relation between pressure unit and length unit is given by $\psi = \rho_w gh$ where $g = 9.81 \text{ m s}^{-2}$ is the gravitational acceleration. In soil physics practice, often used units for pressure head are cm and hPa, and we can set $h = 1 \text{ cm}$ approximately equal to $\psi = 1 \text{ hPa}$.

Soil water potential in unsaturated conditions is a negative number, because it requires energy to transfer soil water from an unsaturated soil to the reference state. To avoid the negative sign and to represent the matric potential as positive number, which also allows to express the potential on a logarithmic scale, the term "suction" and "tension" are used to express pressures or pressure heads as positive variables. Dependent on the state of soil dryness, the matric potential and thus the energy state of soil water typically ranges over several orders of magnitude. It is thus convenient to express the potential on a log scale, which intrinsically requires to express the potential as positive number, i.e. as suction. Specifically in mainland Europe, the use of the "pF" value has become established and is frequently used:

$$pF = \log_{10}(|h|) \text{ with } h \text{ in [cm]} \quad (3)$$

where h is the matric potential expressed as pressure head in the unit cm. Although the pF unit may have a somewhat clumsy definition, its usage is widely understood and practical.

The water suction defines a cascade of key moisture states, such as field capacity, permanent wilting point, air dry soil and oven dry state. Table 1 gives a synoptic overview to these states. The uppermost line (pF 0) indicates the almost fully saturated state, where the matric pores are all filled with water and only pores with diameters $>300 \mu\text{m}$, i.e., so-called macropores, are drained. At the other end of the moisture scale are the air dry and oven dry state. These are somewhat affected by the humidity of the ambient air, but the listed values (pF 6.0 and pF 6.9) can be seen as typical for normal environments (e.g., $\sim 50\%$ relative humidity at 20°C).

Measurement of water content

Reference method: Gravimetric measurements

The reference measurement for water content is obtained by determining the mass loss by evaporation of water from a soil sample during oven drying. Samples are typically dried for at least 24 h at 105°C , or longer if mass loss has not ceased. Note that at this condition not all water molecules in a soil are removed from the system. Rather, it is an operational difference of water content between an actual state and a dryness that is defined by the oven dry reference state, as indicated in Table 1. Also, one should be aware that air-dry soil, which is dried at room or outside temperature rather than in an oven, does not have a water content of zero. The difference between air-dry and oven-dry water content can be small for coarse sands but large for fine-textured soils.

Table 1 Water potential units.

	ψ [kPa]	h m H_2O	pF	Pore diameter [μm]	Relative humidity
Quasi saturated	0.1	0.01	0.0	3000	1.00000
	1.0	0.10	1.0	300	0.99999
FC (near GW)	6.0	0.61	1.8	50	0.99996
	10	1.0	2.0	30	0.99993
FC (far from GW)	33	3.4	2.5	9	0.99976
	100	10	3.0	3	0.99926
	1000	102	4.0	0.3	0.99264
PWP	1500	153	4.2	0.2	0.98898
	10^4	1'020	5.0	0.03	0.92877
Air dry	$\sim 10^5$	$\sim 10'000$	~ 6		0.47763
Oven dry	$\sim 8 \cdot 10^5$	$\sim 80'000$	~ 6.9		0.00062

GW: groundwater. FC, field capacity, a typical value for the drained upper limit of water potential in soil; value of pF 1.8 is used in conditions close to groundwater; value of pF 2.5 is used traditionally for conditions far from groundwater. PWP, a typical value for the lower limit of plant-available water in soil. Value for "Air dry" is typical but varies with atmospheric humidity. Value for "Oven dry" is typical but varies with oven humidity and oven temperature. "Pore diameter" is diameter of the largest water-filled cylindrical pore at the indicated potential. Relative humidity is computed assuming a temperature of 20 °C.

Apart from errors in weighing soils before and after oven drying, the two most serious errors come from loss of mass of nonaqueous volatiles in the sample and uncertainty of the point at which the sample is really "dry". Increasing or decreasing the drying temperature changes the mass loss, and this change can be substantial in some soils. Variation in oven humidity can also lead to some uncertainty. Typical errors are on the order of 0.005 kg kg^{-1} . There is a number of faster drying methods which give quicker results at the expense of some accuracy. According to [Campbell and Campbell \(2005\)](#), drying of samples in a microwave oven can decrease the time required for a measurement to approximately 20 min, while still giving acceptable accuracy for many purposes.

Reference method: Volumetric measurements

Mass wetness is easily determined in laboratory studies, but has little relevance in the field, where one is mainly interested in the ability of the soil to store water for later transpiration and evaporation. Here volume wetness is the relevant measurement. The direct method for measuring volume wetness is to determine the water mass through oven-drying, computing from it the water volume, and relating this to a sample of known volume. Soil cores taken by pressing sharpened steel cylinders of 100 cm^3 , 250 cm^3 or even larger are used to obtain samples of known volume. In collecting the sample, utmost care must be taken not to compress the soil core by the sampling process. From the known volume and the soil dry mass, the bulk density is calculated. The volume wetness is then obtained using Eq. (1). Since this is a tedious and time-consuming measurement, which furthermore is subject to large uncertainty owing to the large spatial variation found in the field, volume wetness is often inferred in situ from measurements of other soil properties.

Sensor technology for dielectric properties

Destructive sampling to measure soil water content is time-consuming, can interfere with plots and only measures one point in time. Sensors connected to data loggers are therefore commonly used to measure water content. Dielectric sensors determine the relative electric permittivity, ϵ [–] (formerly: dielectric constant) of the soil. The permittivity is then converted to a soil moisture content measurement using a calibration equation, which can be either empirical ([Topp and Davis, 1985](#)) or based on theoretical considerations ([Roth et al., 1990](#)). The relative dielectric permittivity of water is approximately 80 at microwave frequencies, whereas it is between 3 and 5 for soil minerals, organic matter, and ice. A measure of soil permittivity is therefore strongly influenced by the amount of liquid water present in the soil. Since ice has a dielectric permittivity near that of soil minerals, dielectric methods measure unfrozen water content in frozen soil.

Dielectric sensors are commonly used for soil moisture measurement in research and agricultural applications because they are (as such) relatively accurate, durable, and can provide continuous measurements over time. Thus, sensors of this type have become dominant for the past 30 years or so for soil moisture monitoring purposes. Three methods are typically used to measure the permittivity of the soil: time domain reflectometry (TDR), frequency domain reflectometry (FDR), and capacitance. [Fig. 1](#) gives an overview of water content sensors that were used in a sensor comparison study by [Jackisch et al. \(2020\)](#). A variety commercially available sensors is listed in [Table A1](#) in the appendix.

Time domain reflectometry (TDR)

The TDR sensor works by sending a high-frequency electromagnetic signal down a probe inserted into the soil. Parallel conductors are placed in the soil forming a transmission line, and one the time required for an electromagnetic pulse to traverse the

	System name	Manu- facturer	Measurement principle ^{*1}	Probe length, integral volume ^{*2}	Range	T ^{*3}	Image
Soil water content	Trase TDR Trase	TRASE	TDR (tangent intersection of pulse in 10 ps)	20 cm, ≈ 1000 cm ³	0 – 1 m ³ m ⁻³		
	Trime Pico32 Pico32	IMKO	TDR (time sampling of 1GHz TDR pulse in 3 ps)	11 cm, ≈ 250 cm ³	0 – 1 m ³ m ⁻³	•	
	Trime Pico64 Pico64	IMKO		16 cm, ≈ 1250 cm ³	0 – 1 m ³ m ⁻³	•	
	Trime T3P T3P	IMKO	(11 cm guides on tube probe)	11 cm, ≈ 1000 cm ³	0 – 1 m ³ m ⁻³		
	ThetaProbe ML2x	Delta-T	I (impedance of 100 MHz signal)	6 cm, ≈ 75 cm ³	0 – 0.5 m ³ m ⁻³	•	
	HydraProbe Hydra	Stevens	I (impedance of 50 MHz signal)	4,5 cm, ≈ 40 cm ³	0 – 1 m ³ m ⁻³	•	
	10HS	METER (Decagon)	I (impedance of 70 MHz signal)	10 cm, ≈ 1300 cm ³	0 – 0.57 m ³ m ⁻³		
	5TM	METER (Decagon)		5 cm, ≈ 715 cm ³	0 – 1 m ³ m ⁻³	•	
	EC5	METER (Decagon)		5 cm, ≈ 250 cm ³	0 – 1 m ³ m ⁻³		
	WET 2 WET	Delta-T	I (20 MHz signal on central rod)	6.8 cm, ≈ 500 cm ³	0 – 1 m ³ m ⁻³	•	
	Profile Probe PR2/6 PR2	Delta-T	I (100 MHz signal on pairs of steel rings)	6x along tube probe 5 cm, ≈ 3100 cm ³	0 – 1 m ³ m ⁻³

	SMT100 SMT	Truebner	Freq. of TDT ring oscillator	≈ 10 cm	0 – 0.6 m ³ m ⁻³	•	

Fig. 1 Selection of water content sensors, as used in the comparative study of Jackisch et al. (2020). From Jackisch C, Germer K, Graeff T, Andrä I, Schulz K, Schiedung M et al. (2020). Soil moisture and matric potential—an open field comparison of sensor systems. *Earth System Science Data* 12(1): 683–697. Reproduced with courtesy of Copernicus.

transmission line, reflect from the distal end, and return along the same line is measured. The time delay between the transmitted and reflected signals is used to determine the speed of propagation of the electromagnetic disturbance. This speed is controlled by the dielectric permittivity of the surrounding medium. It is computed from

$$\varepsilon = \left(\frac{ct}{2L} \right)^2 \quad (4)$$

where c is the speed of light ($3 \times 10^8 \text{ m s}^{-1}$), t [s] is the time to traverse the transmission line, and L [m] is the length of the transmission line. TDR measurements obviously require very fast response circuitry. The time resolution must be on the order of 100 ps. Equipment with this kind of time resolution is necessarily relative expensive. TDR, due to its higher-frequency excitation, is less influenced by electrical conductivity of the soil than the capacitance-based probes. See also Chapter entitled Time-Domain Reflectometry.

Capacitance probes

Capacitance probes provide a cheaper alternative since slower circuitry is connected to the transmission line. A voltage pulse is applied through a resistor of value R and the transmission line acts like a capacitor, with the soil as the dielectric. The time constant for charging the capacitor (time to charge to 63% of its final voltage) is RC , where C is the capacitance of the probe. The capacitance is related to geometric factors and is directly proportional to the dielectric permittivity of the medium surrounding the probe. The charging time is therefore directly related to the soil permittivity. Capacitance probes are relatively inexpensive and easy to operate. Furthermore, the sensor geometry is very adaptable, facilitating the development of a variety of configurations and making them particularly usable for use in solid phase (SPS) matric potential sensors (see section “Measurement of water potential”). However, capacitance probes are influenced by soil type and require calibration. Also, there is concern about the influence of soil salinity and soil temperature on capacitance sensors (Kelleners et al., 2004).

Frequency domain reflectometry (FDR)

FDR probes are also used to measure the capacitance, based on the change in frequency of a reflected radio wave or resonant frequency (Kelleners et al., 2004). In this measurement method, an oscillator is used to pass an electromagnetic signal through a metal waveguide. FDR probes are considered accurate, but must be calibrated for the type of soil in which they are buried. Compared to TDR probes, they offer a faster response time. However, the term FDR is often misused because most frequency sensors use a single frequency rather than a frequency range.

Sensor technology based on electric conductivity

When accuracy must be weighed against affordability and a cheap sensor is needed, a Raspberry Pi moisture sensor is an option. The physical measurement principle involves measuring the electrical conductivity or resistance of the soil to determine its moisture content. The physical measurement is usually implemented using simple circuits and analog-to-digital converters (ADCs) to interface with the Raspberry Pi. The analog readings from the sensors are converted into digital values that can be processed and interpreted by the Raspberry Pi for further analysis. The method provides a general indication of soil moisture. It is not as accurate as more advanced commercial sensors, but can still be useful for simple projects or experiments in various fields such as agriculture, gardening, or environmental monitoring. Adjustments and calibrations are required depending on the application and environmental conditions.

Sensor technology for thermal properties

Both thermal conductivity and heat capacity of soil vary with water content. The relationship with heat capacity is an easy one to use for determining water content. The water content can be computed from the volumetric heat capacity of soil:

$$\theta = \frac{C - C_s}{C_w} \frac{\rho_b}{\rho_s} \quad (5)$$

Here C , C_s , and C_w [$\text{J m}^{-3} \text{ K}^{-1}$] are the volumetric heat capacities of the bulk soil, the soil minerals, and water; and ρ_b [kg m^{-3}] and ρ_s [kg m^{-3}] are the bulk and particle densities. Since C_w is typically about twice as large as C_s , changes in water content have a fairly large effect on C . If the bulk density of the soil is known and C is measured, all values on the righthand side of Eq. (5) are known, so water content can be computed. Typically, C is measured using a dual-needle thermal properties sensor. In the recent Tensiomark™ sensor, the sensor element is imbedded between two porous ceramic plates. The sensor head is glued into a approx. 125 mm long plastic case, in which the electronics are situated. Fig. 1 includes this and other sensors of the heat dissipation type.

As indicated above, an impressive variety of dielectric and thermal sensors is commercially available (Table A1). A common problem to all such sensors is the rather limited support volume. Since soil-embedded sensors measure the properties of the dielectric within the electromagnetic field of the probe or transmission line, it is important that a representative sample of the soil lies within the electromagnetic field of the sensor. Unfortunately, this field lies close to the surface of the sensor, so any air gaps or compaction around the sensor may adversely affect the measurement. This problem is less given for sensors based on gamma ray attenuation or thermalization of fast neutrons, described next.

Sensor technology for nuclear methods

Gamma rays and neutrons both interact strongly with soil water. The methods used most widely for water-content measurement involve attenuation of transmitted gamma radiation and backscattering of neutrons, though neutron transmission and gamma backscatter have also been used. Gamma attenuation is typically a laboratory method. A soil column, 5–20 cm thick, is irradiated by a collimated beam of gamma radiation. Sources with appropriate energy levels are ^{137}Cs and ^{241}Am . The volume wetness is computed from:

$$\theta = \frac{\ln\left(\frac{I_d}{I_w}\right)}{\mu_w S} \quad (6)$$

where I_d and I_w are the numbers of gamma photons passing through the dry and wet soil in unit time, respectively, μ_w is the mass attenuation coefficient for water, and S is the soil-column thickness. It is possible to determine the bulk density and the water content of a sample without measuring the gamma attenuation in the dry soil column by measuring the attenuation of two gamma beams having different energies.

Neutron scattering is a method for measuring volume wetness in the field. In a typical application, a neutron source such as $^{241}\text{Am}/\text{Be}$ is lowered into an access tube in the soil. The neutrons from the source initially have high energy, but as they collide with low-atomic-mass nuclei (mainly hydrogen) in the soil, they slow and become ‘thermal’ neutrons, with energies typical of atoms at room temperature. These slow neutrons can be counted with a relatively simple detector. Since the main source of hydrogen nuclei in the soil is water, and since the number of scattered neutrons is proportional to the number of collisions with these hydrogen nuclei, there is a relationship between neutron count and water content:

$$\theta = a + b \frac{I}{I_{std}} \quad (7)$$

where a and b are soil-specific empirical constants, I is the count in soil, and I_{std} is the count in a standard scattering medium. Neutron scattering is much less affected by air gaps around the sensor than are dielectric methods. The scattering volume (i.e., the signal support volume) for the neutrons varies with soil-water content from approximately from a sphere of 15 cm diameter in saturated soil to, e.g., 70 cm in dry soil.

Noninvasive techniques

The spatial characteristics of soil moisture data can be characterized using the “scale triplet” proposed by Blöschl and Sivapalan (1995), encompassing support, spacing, and extent. The support refers to the integration volume of the measurement methods, the spacing to the distance between single measurements, and the extent to the area over which measurements are available (e.g., area of measurement network). Embedded soil moisture sensors have very small support, and spacing and extent depends on the number of sensors that can be placed and managed. To obtain moisture patterns at the km scale relevant to land surface and atmospheric models, they are of limited use.

Intensive progress is thus currently on-going with respect to techniques that allow continuous noninvasive and contactless measurements of soil moisture dynamics at the field to basin scale. According to Bogaen et al. (2015) these are (1) cosmic-ray neutron probes, (2) Global Navigation Satellite System reflectometry, (3) ground-based microwave radiometry, (4) gamma-ray monitoring, (5) terrestrial gravimetry, and (6) low-frequency electromagnetic surface waves. The treatment of these techniques is beyond the scope of this Chapter. However, we must be aware that any of these techniques produces proxies of soil moisture with different characteristics. They all depend on ground truth measurements for calibration, and they all are also affected more or less by vegetation, snow, atmospheric conditions, land surface properties, and other factors.

As a single example, cosmic ray neutron sensing receives currently considerable attention in the scientific community. It is used to measure the average soil moisture at the horizontal scale of 10^2 m and depth of a few decimeters. A stationary probe measures neutrons produced by cosmic rays and moderated by hydrogen atoms, which are mainly found in soil water, and emitted into the atmosphere. There they are mixed on a scale of hundreds of meters and inversely correlated in density with soil moisture. A neutron detector captures all neutrons of a specific medium energy range that cross its path. To get meaningful readings, the instruments capture the surrounding neutrons over a period of hours. Since their number is very small, natural fluctuations introduce large errors into the measurements. In addition, water that is bound in plants or even snow falsify the measured values. Even cattle that curiously approach the sensors can be a source of error.

Measurement of water potential

Water potential in soils ranges from a pressure head $h = 0$ at full saturation to air dry ($\sim \text{pF } 6$) or even oven dry ($\sim \text{pF } 6.9$) conditions, where water content is zero. The available methods for soil water potential measurement differ with respect to the suction range in which they are applicable. No single instrument or method exists that is able to capture soil water potential measurement across the full range, from saturation to oven dryness. In the wet and moist range, the pore water pressure of the soil is measured directly with tensiometers. In the medium range of moisture content, porous reference media (solid phase sensors, SPS) in which the degree of water saturation changes with water potential, are suitable. Gypsum blocks, granular matrix sensors, heat dissipation matric

potential sensors and filter paper are examples. In relatively dry soils, water potential can be derived from vapor pressure measurements by psychrometry. All methods for measuring soil water potential require hydraulic equilibrium between soil water in the domain in contact with a sensor and the measurement device itself. The contact requires connection of the water phase from the soil to the inside of the sensor, except for psychrometers, where contact is provided by the vapor phase. In this section, we describe the principles of these measurement techniques, with an emphasis on tensiometer measurements.

Tensiometers—direct potential measurement in the wet range

Tensiometers for matric potential determination are historically the earliest used measurement technologies for soil water potential in the field. The fundamental principles go back to the seminal work of Willard Gardner, while Lorenzo A. Richards is credited with developing the first durable tensiometer design suitable for field use in the 1920s. According to Or (2001), historical evidence suggests that the initial design was actually proposed even earlier, by Burton E. Livingston as far back as 1908. Tensiometers are particularly suited for measurement of soil water energy status at high water contents where transport processes are relatively rapid (e.g., solute transport from the vadose zone down to groundwater). However, due to their limited measurement range, they cannot be used in drier conditions, where soil water becomes limiting for plant growth. Under relatively moist soil conditions, tensiometric measurements are robust, reliable, and accurate, with a considerable body of theoretical and practical knowledge gained by soil physicists, hydrologists, manufacturers, and other practitioners. However, tensiometers require maintenance and their use at frozen conditions is problematic. In the following, we discuss principles of tensiometric measurements, tensiometer design and measurement range, and show recent developments. Reviews on all aspects of the practical applicability of tensiometers are available for further information, e.g., by Young and Sisson (2002), Durner and Or (2005), and Whalley et al. (2013).

A tensiometer generally consists of a water-filled reservoir connected to a pressure sensor (manometer or electronic pressure transducer), which is brought into contact with the soil via a rigid porous membrane that is permeable to water and impermeable to air. In most cases, the membrane is in the form of a porous ceramic cup with size of a few cm, and pure water is used as the internal pressure transfer fluid. The water phase outside the cup and the liquid in the interior of the tensiometer are bridged through water-filled fine pores of the cup. Water flows between the surrounding soil and the water-filled reservoir until the suction inside the tensiometer is equilibrated to the soil's matric potential. In modern tensiometers, the interior is almost perfectly rigid. If no air bubbles are present, the change in water volume in response to matric potential changes is negligible, resulting in almost instant equilibrium and a quick response time of the instrument. Following pressure equilibration, the liquid pressure in the tensiometer is directly measured. To function properly, the pores of the membrane must remain impermeable to the non-wetting fluid (air), i.e., they must remain at all operation states completely saturated with water. Tensiometers measure the matric potential component of the water potential. The pore openings of the membranes are in the μm range, which is still about 6000 times larger than the size of a hydrated Na molecule (Young and Sisson, 2002), making them permeable to dissolved ions. Therefore, the pressure measured inside the porous cup is not affected by the osmotic potential component. Still, the pores are small enough to withstand an air entry up to some bar pressure difference.

Installation of tensiometers is straightforward. The porous cups are usually connected to a shaft of specific length that allows them to be inserted at a desired measurement depth into pre-drilled access holes. The diameter of the access hole at the target depth is slightly smaller than that of the porous cup to ensure adequate contact. In principle, a partial contact between the cup and the surrounding material would be sufficient, since the contact area does not influence the equilibrium pressure, but it will affect the response time. Also, a change of the material properties near the cup, for example by compression of the surrounding soil, has minimal influence on the measured value of the soil water potential, because the energy status is continuous for different porous materials in hydraulic equilibrium. In stony soils, where the contact area of the soil's water phase to the tensiometer cup can be very small, it may be advantageous to facilitate water pressure transfer by inserting a slurry of silica flour into the borehole. In contrast to the water content, the water potential in soils does not change abruptly at the material boundaries. Despite this spatial continuity of the state variable, however, experience shows that, especially in the presence of roots, the local variability of the matric potential can become very high as soon as the soils begin to dry out.

In general, it is not the absolute pressure of the soil water that is of interest, but the capillary pressure, which is defined as the pressure difference between the water and the gas phase in the soil. Therefore, the pressure sensors used for tensiometers are usually differential sensors that measure the difference between the pressure in the tensiometer cell and the ambient air pressure. This atmospheric reference air pressure is in most cases equal to the gas pressure at the location of the measurement. However, there are cases where rainfall traps a layer of air between a sharp wetting front and the groundwater, significantly increasing the atmospheric pressure. Furthermore, in soils that are very wet and where the continuity of the gas phase is limited, the local pressure of the trapped air is not identical to the ambient air pressure, adding a pneumatic component to the water potential. When tensiometric pressure is interpreted as matric potential in such cases, it is a misunderstanding and contributes to a class of phenomena called "dynamic effects" (Durner et al., 2014).

In the past, U-manometer tensiometers with pressure measurement by mercury, mechanical manometer tensiometers and septum tensiometers were used, but they have lost their importance, not least because of poor sensitivity (see section "Measurement characteristics of water potential sensors", below). Modern tensiometers measure the water pressure in the reservoir with electronic pressure transducers. Features of such tensiometers are integrated amplifier, digital signal conditioning for the electrical output, temperature compensation, filling level indication, and the possibility for external refilling in situ. Fig. 2 shows the setup of a commercially available modern tensiometer for field use with a cup diameter of 20 mm (left), and a tensiometer for laboratory use

Fig. 2 Advanced pressure transducer tensiometers. Left: Pressure transducer tensiometer T8 by UMS. Right: Mini tensiometer T5 by UMS. Reproduced by permission of METER Group AG, Munich, Germany.

with a cup diameter of 5 mm (right). Comparative studies have shown that the size of the tensiometer cup is irrelevant for measuring matric potential, and apart from the problem of mechanical robustness, small tensiometers can perform excellently, even in field use (Jackisch et al., 2020).

The main disadvantage of tensiometers is their limited measuring range. Under thermodynamically stable conditions, the requirement that the water inside the tensiometer must be able to transfer the suction, requires an absolute liquid pressure which is above the vapor pressure at ambient temperature. When the absolute pressure in the tensiometer goes below the water vapor pressure, cavitation of the water phase occurs followed by spontaneous boiling of water. This limits the measurable suction to the pressure difference between the actual ambient atmospheric pressure and the internal vapor pressure. Once a bubble is there, it expands and water is sucked through the porous membrane into the dry surrounding soil, and the tensiometer acts essentially as a micro-irrigation device. In practice, measurements are often reliable only up to ~ 80 kPa ($\sim pF$ 2.9). However, thermodynamic equilibration can be delayed, expressed as a boiling delay (deferescence). This metastable state can prevail for extended periods of time and allows an extension of the tensiometric measurement range. The theoretical limit of suction is given by the energy required for cavitation in a pure water phase, which requires a calculated tensile strength of 140 MPa (Zheng et al., 1991). Physically reachable maximum suctions are far from this limit, but Temperley and Chambers (1946) reported that thoroughly degassed liquids in smooth-walled containers can have a tensile strength of up to 10% of the theoretical value. Ridley and Burland (1994), at Imperial College London, developed a miniature pressure transducer in which the volume of water between the pressure transducer and the porous stone was minimized and reported measured water potentials down to -1500 kPa with a response time of a few minutes. However, it appears that reliable tensiometers of this type are not commercially available. Practical limits with the best commercial laboratory tensiometers filled with completely gas-free water are in the range of -100 to -400 kPa (Schindler et al., 2010).

In an effort to extend the measurement range of tensiometers, the introduction of so-called osmotic tensiometers has been repeatedly reported. In principle, a tensiometer cup with much narrower pores, which acts as a semipermeable membrane, is filled with a solution with a high osmotic potential, such as polyethylene glycol. In contact with free water, a very high overpressure builds up in the tensiometer interior, e.g., of 1500 kPa. In contact with soil, the soil water suction reduces this positive pressure, theoretically until cavitation occurs inside of the osmotic tensiometer. Earliest efforts date back to the Peck and Rabbidge (1969) who used polyethylene glycol with a molecular weight of 20,000 to extend the measurement range to a water potential of -1500 kPa. Experience has shown that the practicability of the osmotic tensiometer is limited and many difficulties stand in the way of a routine application, despite recent attempts with improved membrane materials and sensor configurations. Key problems

are temperature sensitivity, sensor drift and leakages of the osmotic solutions. Recent developments and an overview about the state of the technique are reported by Van Der Ploeg et al. (2009) and Rahardjo et al. (2021).

Solid-Phase Sensors (SPS): Potential measurement in the medium suction range

Measurement of soil matric potential in the intermediate pressure range (-10 kPa to -5000 kPa) poses considerable experimental challenge. Solid phase sensors (SPS) consist of equivalent porous media (gypsum blocks, granular matrix material, felt, filter paper) embedded in the soil. The soil water pressure of the surrounding soil equilibrates with the pressure inside the porous media by drawing water out of the SPS (when drying) or releasing it into the SPS (when wetting). Internal water content is measured and the corresponding suction in the sensor is calculated from an internal calibration function (actually the water retention curve of the SPS material). In essence, the problem of suction measurement is replaced by a water content measurement in a sensor. The principles for measuring internal water content in the SPS can vary, and basically any principle discussed for direct water content sensors can be used for measurement in SPS. Common sensors use either electrical resistance, heat dissipation, or dielectric properties of the sensor material.

Classic equivalent porous media materials are filter papers, blocks of gypsum, fiberglass or nylon. Also, granular matrix sensors have become available which consist of gypsum wafers embedded in granular matrix (Scanlon et al., 2002). SPS measure only the matric potential as they are permeable for the gas phase in their operation range and neither pneumatic potential nor osmotic potential contribute to the signal. Since SPS require a certain amount of water to flow from the sensor into the soil (drying) or from the soil into the sensor (in a wetting period) there are system-related disadvantages in terms of response time. In addition, hysteresis is unavoidable, so that in phases of transient moisture changes of the surrounding soil the sensor's accuracy may be limited.

The pore-size distribution of the SPS material can be customized to provide a high sensitivity in a desired matric potential range. Modern SPS are suited to measure potentials in the range -10 to -1000 kPa. Promises by manufacturers that their sensors will cover larger ranges should be treated with skepticism. For any SPS, there is a certain suction threshold, below which the porous medium of the sensor is fully saturated and cannot register changes in matric potential. On the other side of the suction range, above a certain suction, the sensor's porous material is rather dry and again further changes in suction will no longer lead to a significant change of water content. Or and Wraith (1999) and Noborio et al. (1999) identified a need for porous materials having a wide range of pore sizes. Or and Wraith (1999) reported a tradeoff between the sensor's matric potential range and its sensitivity to changes in the surrounding soil. Wraith and Or (2001) proposed that equivalent porous media of sensors should have similar particle and/or pore-size distributions as the surrounding soil under investigation.

In the following, we shortly characterize traditional Gypsum blocks, dielectric matric potential sensors, head dissipation sensors, and for historic reasons the filter paper method. Dielectric and heat-dissipation undergo an intense commercial development. A current list is provided in Table A2, and a couple of sensors used in a field comparison study by Jackisch et al. (2020) is shown in Fig. 3.

Gypsum blocks with embedded electrodes to measure the electric resistance have been used for more than 80 years in agricultural applications (Buoyoucos and Mick, 1940). The electrical conductivity in these blocks is buffered by the ion strength of the saturated gypsum solution (~ 0.2 S/m). This is contrary to nylon and fiberglass blocks, where the electrical conductivity is dependent also on the ionic strength of the soil solution. The problems of gypsum block sensors are a limited temporal stability, a long response time, appreciable hysteresis, and the need for individual calibration. Furthermore, the measurements are temperature dependent and

Fig. 3 Example of a capacitance sensor embedded into a porous medium. Reproduced by permission of METER Group Inc., Pullman, WA.

must be corrected accordingly. Handling and disadvantages of these probes are well known and documented (Scanlon et al., 2002), and it appears that not much development has taken place over recent decades.

Dielectric matric potential sensors are made up of a porous equivalent medium in which the water content is measured by TDR, FDR or capacitance technology. Early attempts were recorded by Or and Wraith (1999) and Noborio et al. (1999) who worked with embedded TDR. Nowadays, a wide range of sensors are commercially available in which the internal water content is determined using the capacitance method, and great care is taken to calibrate the sensors with respect to the matric potential. An example of such a sensor is shown in Fig. 4. One difficulty with this type of sensor is placement in undisturbed soil. Unlike tensiometers, it is not sufficient to simply drill a narrow hole from the soil surface to the desired depth; a trench is required from which the sensor is inserted into the soil to accommodate the cabling and sensor geometry.

Although the material properties in the immediate vicinity of the sensor do not directly affect the transmission of water suction from the soil to the sensor, the practical inconvenience of creating a significant disturbance in order to place the sensor should still be taken into account. Basically, this problem is similar to heat dissipation sensors described next.

Heat-dissipation sensors (HDS) were probably first described by Phene et al. (1971) and were critically evaluated by Reece (1996). Here, the matric potential is indirectly inferred by measuring the water content of a porous media based on its thermal properties. The temperature dependence of the heat conductivity makes the heat dissipation sensors very sensitive to the ambient temperature, although corrections of the effect have been developed (Flint et al., 2002). HDS have an outer matrix made of ceramic or felt (e.g., Matile et al., 2013) that encases a stainless-steel needle. Inside the needle is an electrical resistor that runs the length of the probe (typically few cm) and a temperature sensor, either a thermocouple or thermistor. To measure thermal conductivity, a known amount of current is passed through the resistor for a preset amount of time and data are collected on the temperature change over time. The thermal conductivity can be calculated from the slope of the temperature versus the logarithm of time. Because the sensor's matrix properties remain fixed, the thermal conductivity is a measure of the water content of the matrix, which, in turn, is related to the water potential of the soil. These sensors must be calibrated and, at midrange water potentials, have a strong temperature dependence.

Finally, the *filter-paper method* is mentioned here for historical reasons. Contrary to all SPS methods above, it is not suitable for monitoring, but only for a single measurement of a matric potential in a destructive context. A single piece of Whatman No. 42 filter paper is brought in contact with a soil sample until equilibrium, which generally takes 2–3 days. The filter paper is then weighed and dried. The water content of the paper is used to calculate the matric potential using an empirical relationship between the water content of the filter paper and its water potential (Campbell and Campbell, 2005).

The dry range: Determining soil water potential from vapor pressure

If soil water is in temperature and vapor equilibrium with a vapor phase, the potential in the vapor phase becomes the same as that of the liquid phase. The potential in the vapor phase can be determined by measuring its relative humidity. The relation is expressed by the Kelvin equation (Or and Wraith, 1999)

$$RH = e/e_0 = \exp(M_w g h / RT) \quad (8)$$

where RH [–] is the relative humidity, e [Pa] is water vapor pressure, e_0 [Pa] is saturated vapor pressure at the same temperature, M_w is the molecular weight of water ($0.0018 \text{ kg mol}^{-1}$), g is the gravitational acceleration (9.81 m s^{-2}), R is the ideal gas constant ($8.31 \text{ J K}^{-1} \text{ mol}^{-1}$), and T is the absolute temperature [K]. The relative humidity of the air can be determined either from the wet-bulb depression or from the dew point temperature, using a chilled mirror. Since air is an effective diffusion barrier for most solutes, the corresponding water potential includes the osmotic and the matric potential, which is contrary to water tensiometers and SPS sensors.

Psychrometers measure the difference between a dry bulb and wet bulb temperature. The dry bulb is at the temperature of the surrounding soils, the wet bulb at the temperature of an evaporating surface. The lower the humidity, the higher will be the rate of evaporation from the wet bulb, and thus the temperature depression below ambient. Rearranging (Eq. 8) and taking a log-transformation leads to

$$h = \frac{RT}{M_w g} \ln(e/e_0) \quad (9)$$

For the range of e/e_0 near 1, which is the usual state in soils in humid climates, Eq. (9) can be simplified to

$$h = \frac{RT}{M_w g} \left(\frac{e}{e_0} - 1 \right) = 0.471 \cdot 10^6 \text{ T} \left(\frac{e}{e_0} - 1 \right) \quad (10)$$

with h in m (Rawlins and Campbell, 1986).

To determine h , it is feasible to measure the wet-bulb depression or dew-point depression of the air in the headspace. However, for soil that is moist enough to support plant growth, the relative humidity is typically above 0.99 (Table 1). This means that the psychrometer or dew-point meter used must be exceptionally precise and sensitive with respect to wet vs. dry temperature measurements. To obtain precise psychrometric water potential measurements of around -10^5 kPa , the accuracy required for temperature difference measurements is 0.005°C .

Fig. 5 Field thermocouple psychrometer. From: Muñoz-Carpena R (2004) *Field devices for monitoring soil water content: BUL343/AE266*, 7/2004. Edis 2004(8).

A soil psychrometer for use in the field consists of one junction of the thermocouple suspended in a thin-walled porous ceramic or stainless screen cup buried in the soil (Fig. 5). Another thermocouple is embedded in an insulated plug to measure the ambient temperature at the same location. The *RH* in the air chamber is calculated from the “wet bulb” vs a reference “dry bulb” temperature difference. By an electrical current, the suspended thermocouple is cooled below the dew point until water condenses on the junction. The cooling current then stops, and as water evaporates, it draws heat from the junction, depressing it below the temperature of the surrounding air until it attains wet bulb temperature. The difference in temperatures between the wet and dry bulb is related to the relative humidity by the psychrometer equation

$$\frac{e}{e_0} = 1 - \left(\frac{s + \gamma'}{e_0} \right) \Delta T \quad (11)$$

where s is the slope of the saturation water vapor pressure curve ($s = de_0/dT$), γ is the psychrometric constant ($\sim 0.067 \text{ kPa K}^{-1}$ at 20°C), and ΔT is the temperature difference (K) between the dry and wet bulb.

Due to their sensitivity to thermal gradient effects, psychrometers are not suitable for use at shallow soil depths. Additionally, the requirement for equilibrium among different phases causes psychrometers to have a relatively slow response time.

Theoretically, it is not necessary to calibrate the calculation of the total water potential for specific soils since it is based on fundamental physical principles. However, in practice thermocouple psychrometers are calibrated empirically using solutions of known water potential. The measurement range for water potential toward the wet end is approx. -30 to 200-kPa , whereas in the dry range it reaches -300 MPa . For further details, the reader is referred to Andraski and Scanlon (2002).

In lab instruments, water potential is measured by equilibrating the liquid phase water of a sample with the vapor phase water in the headspace of a closed chamber. The dew point depression technique has proven to be a fast and accurate method for determining water potential. A widely used instrument of that type is shown in Fig. 6 (e.g. Gubiani et al., 2013; Schelle et al., 2013). It uses a chilled mirror dew point technique to measure the water potential. A thermoelectric (Peltier) cooler controls the mirror temperature. A beam of infrared light is directed onto the mirror and reflected back to a photodetector, which detects the change in reflectance when condensation occurs on the mirror. A thermocouple attached to the mirror accurately measures the dew-point temperature. Since both dewpoint and sample surface temperatures are simultaneously measured, the need for complete thermal equilibrium is eliminated, and measurement time is reduced to less than 5 min. Readings are reported directly in MPa, with accuracy for the water potential range of 0 to $-10 \text{ MPa} \pm 0.1 \text{ MPa}$ and from -10 MPa to $-60 \text{ MPa} \pm 1\%$. This reflects exceptional accuracy of differential temperature measurements, as an accuracy of $\pm 0.1 \text{ MPa}$ requires a dew point temperature accuracy of $\pm 0.001 \text{ K}$.

Measurement characteristics of water potential sensors

All of the water potential measuring instruments discussed in this chapter affect the signal to be measured. The measurement characteristic of an instrument is determined by the relation between the sensitivity and the conductance of the instrument. The sensitivity expresses the ratio between the change of the signal (pressure change Δp) with respect to the amount of water ΔV that is required to flow from the surrounding soil to (or from) the instrument (Richards, 1949),

$$S = \Delta p / \Delta V \quad (12)$$

The conductance is dependent on the area of exchange between the instrument and the soil, and on the flow resistance of the instrument. In the case of tensiometers, this resistance is determined by the thickness and the saturated conductivity of the porous membrane. The conductance of SPS instruments is established by the (un)saturated conductivity function of the equivalent porous medium (EPM). Additionally, the capability of the adjacent soil to deliver the necessary water flow needs to be considered.

For modern advanced tensiometers that are perfectly filled, the measurement characteristic is very good for the whole measurement range, due to the high sensitivity of the pressure transducers and the fact the ΔV is close to zero. In the case of SPS with equivalence porous media, it is dependent on the volume and porosity of the sensor, its unsaturated conductivity, but also on

Fig. 6 WP4C Dewpoint PotentialMeter. Reproduced with courtesy of METER Group Inc., Pullman, WA.

the unsaturated conductivity of the surrounding soil. In principle, the sensitivity of SPS is lower, since the water content of the sensor must change. In an ideal SPS, the porosity characteristic of the sensor would be equal to the soil itself (Wraith and Or, 2001). For psychrometric methods, the measurement characteristic might be limited by the required equilibration of the gas phase vapor pressure and temperature.

Concluding remarks

This chapter highlights techniques for measuring soil water content and energy state. All described techniques are limited to small volumes of measurement. In the future, there is potential for larger scale estimation of water content in areas and volumes, particularly near the earth-atmosphere interface, through the use of proxies such as ground penetrating radar, electrical tomography, cosmic ray sensing, or passive microwave radiation mounted on satellites or drones. Despite this, local in situ measurements will remain necessary to obtain accurate ground truth and understand vertical flow and transport processes in soils. To this end, there has been ongoing development of commercially available water content sensors using dielectric methods (Table A1), including sensors with wireless communication and profile probes. Nonetheless, the primary challenge in the field remains soil heterogeneity in conjunction with small measurement volumes and the practical issue of correctly placing the sensors in the soil undisturbed (Stevenson et al., 2021). Consequently, interpreting absolute water content from individual sensors remains uncertain.

The challenge of measuring water potential is particularly difficult. The problem of accurately measuring suction in the field over a significant distance or area remains unsolved, compounded by the fact that no single matric potential sensor can cover the entire suction range from saturation to air dryness. Tensiometers provide measurements in suction ranges of about 0–10² kPa, SPS sensors cover (in an optimistic view) the range 10¹–10⁴ kPa, and thermocouple psychrometers can achieve measurements within a range of 10^{2.5}–10⁵ kPa. The accuracy of modern tensiometers is excellent, but their practical use is restricted, as they need to be refilled when they run dry, and cannot function until the soil moisture conditions improve. To overcome these limitations, technical development focuses on SPS sensors despite their principal drawbacks (Table A2). However, there is still a lack of rigorous scientific proof of their long-term reliability in field measurements, and in some cases, the results of studies appear to contradict some manufacturers' claims (Jackisch et al., 2020).

Abstract

The relations between the amount of water retained in unsaturated soils and the retaining capillary and adsorptive forces are described by the soil water characteristic (SWC) curve. This function is soil specific and plays an important role in many agricultural, environmental, and engineering applications. A soil specific SWC is used for crop water management and determining plant available soil water, for representing water flow and contaminant transport, and for assessing natural disasters such as flooding or landslides. This chapter presents fundamental and novel concepts and techniques for representation and quantification of the SWC curve and estimation of its parameters at local and global scales. Standard measurement methods such as the Richards pressure plate apparatus and Tempe cells are presented along with contemporary techniques based on chilled-mirror dewpoint psychrometry, dielectric measurements and dynamic evaporation. We review different pore space representation models, the concept of hysteresis, and discuss adsorptive forces that dominate the dry end of SWC.

Key points

- Novel and established concepts for representation and modeling of the soil water characteristic curve are presented
- Standard soil water characteristic curve measurement methods are described along with contemporary state-of-the-art techniques
- Various pore space representation models, the concept of hysteresis, and the contribution of adsorptive forces to soil water retention are discussed

Introduction

The soil water characteristic (SWC) curve describes the amount of water retained in the soil pores (expressed as mass or volume water content, θ_m or θ_v) under equilibrium at a given matric potential. The SWC is an important hydraulic property related to the size and connectedness of pore spaces, hence, is strongly affected by soil texture and structure, and by other constituents, including organic matter and clay minerals. Modeling the water distribution and flow in partially saturated soils requires knowledge of the

Fig. 1 Measured SWC data pairs (symbols represent a matric potential value and a corresponding water content) for Millville silt loam soil shown with a continuous SWC parametric model (to be discussed below).

SWC, therefore it plays a critical role in water management and in the simulation of solute and contaminant transport in the environment. Typically, a SWC is highly nonlinear and relatively difficult to measure accurately. Because the matric potential (ψ_m) extends over several orders of magnitude for the range of water contents commonly encountered in practical applications, the matric potential is often plotted on a logarithmic scale. Fig. 1 depicts SWC measurements together with a fitted continuous SWC model for Millville silt loam soil.

The matric potential

The matric potential represents the change in energy state of soil water relative to a reference, and it is the component of water potential attributed to the effects of capillary and adsorptive forces acting between the liquid, gas, and solid phases. Capillarity in unsaturated soils originates from the formation of curved air-water interfaces that, due to the resulting air-water surface tension and the contact angle, cause a lowering of the pressure in the liquid phase relative to the gas phase. Hence, capillarity in soil emerges under partially saturated conditions (i.e., in the presence of the nonwetting air phase), where based on simple radial geometry, a meniscus curvature radius (R) is a function of the pressure difference between air and water (termed capillary pressure, P_c) expressed by the Young–Laplace equation:

$$P_0 - P_c = \Delta P = \frac{2\sigma}{R} \quad (1)$$

where P_0 is the atmospheric pressure (conventionally referenced as zero), P_c is the pressure of the liquid side of the meniscus (in soil water), and σ is the surface tension of the air-water interface. If soil pores were to behave as a bundle of capillary tubes, the relationships between matric potential and soil pore radii would be described by these relations alone. However, in real soils, forces other than capillarity are at play and give rise to adsorption of water to soil surfaces to form thin liquid films. Generally speaking, the amount of water associated with water films scales with the soil specific surface area, hence, adsorptive forces are most important in clayey and organic soils with large specific surface areas. Additionally, water films are affected by electrostatic forces most prominent in soils with appreciable active clay content (e.g., montmorillonite). In sandy soils, adsorption is small (because the surface area is low) and capillarity dominates the SWC. Generally, the soil matric potential reflects the combined effects of capillarity and surface adsorption, which are often difficult to separate (see Water Potential and Capillarity chapters).

The bundle of cylindrical capillaries model

Conceptual models for the SWC and liquid distribution in partially saturated porous media have evolved based on the “bundle of cylindrical capillaries” (BCC) representation of pore-space geometry. The BCC representation postulates that at a given matric potential a portion of interconnected cylindrical pores is completely liquid-filled, whereas larger pores are completely empty (Fig. 2). This convenient idealization of soil pore space enables a linkage between the soil pore size distribution and the SWC based on the capillary-rise equation. (see Capillarity and Macropores and Macropore Flow chapters). However, such representation

Fig. 2 Relationship between the pore space, as represented by the bundle of cylindrical capillaries model, and the SWC. Greater capillary rise against the pull of gravity occurs in smaller pores, which have smaller radii of meniscus curvatures. Note that z indicates the elevation above free water (representing the gravitational force), θ_a stands for pore volume, θ_v for volumetric water content, and θ_s for volumetric water content at saturation.

imposes serious limitations on the practical application of the BCC model to natural porous media as discussed in the following section, including the unrealistic underlying geometry that precludes dual water–air occupancy within the same pores and lack of consideration of adsorbed water films.

Liquid retention and pore shape

Liquid retention in the porous matrix of a soil is highly dependent on the shape and angularity of individual pores. The inspection of a thin section of Devonian sandstone (Scholle, 1979) (Fig. 3A) and a scanning electron micrograph of calcium-saturated montmorillonite (Fig. 3B) reveals that natural pore spaces do not resemble cylindrical capillaries, as assumed for the BCC model. When angular pores are drained, a fraction of the wetting phase remains in the pore corners (Fig. 3C). This aspect of “dual occupancy” of the invaded portion of the tube, not possible in cylindrical tubes, more realistically represents liquid configurations and mechanisms for maintaining hydraulic continuity in porous media. Liquid-filled corners and crevices play an important role in displacement rates of oil and in other transport processes in partially saturated porous media. The relationships between liquid retention and pore angularity as well as dynamic wetting phase displacement processes (i.e., pore snap-off and snap-on) are known and well documented (Tuller et al., 1999).

Representing the SWC

Measuring the SWC is laborious and time-consuming. Measured ψ_m - θ pairs are often fragmentary and usually constitute relatively few measurements over the wetness range of interest. For modeling and analysis purposes, and for characterization and comparison between different soils and scenarios, it is therefore beneficial to represent the SWC in a mathematically continuous form. Several approaches, ranging from empirical parametric expressions to physically based models with parameters derived from measurable medium properties to pore network or lattice Boltzmann simulations can be employed to represent the continuous SWC.

Parametric SWC models

Various expressions have been proposed to represent the shape of SWC using continuous and differentiable functions. These are often empirical relations requiring a few parameters. The commonly used functions have been selected for their parsimony (as few parameters as possible), simple and consistent parameter estimation, and close fit to measured θ - ψ_m values including the wet and dry limits (wet and dry ends). Among the many models we present here are the widely used parametric SWC models proposed by Brooks and Corey (1964) and by van Genuchten (1980). The van Genuchten (VG) model relates the relative saturation (Θ) to the matric potential by the following expression:

$$\Theta = \frac{\theta - \theta_r}{\theta_s - \theta_r} = \left[\frac{1}{1 + (\alpha \psi_m)^n} \right]^m \quad (2)$$

where θ_r and θ_s are the residual and saturated water contents, respectively, ψ_m is the matric potential, and α , n , and m are parameters directly dependent on the shape of the $\theta(\psi_m)$ curve. Because of the strong correlation between n and m , a common simplification is to assume that $m = 1 - 1/n$. Thus, the parameters required for estimation of the model are θ_r , θ_s , α , and n . θ_s is relatively easy to measure or can be deduced from soil bulk density, leaving only the three unknown parameters θ_r , α , and n to be estimated from experimental data. Note that θ_r is sometimes taken as θ at -1.5 MPa, $\theta_{air\ dry}$, or a similar low matric potential value.

Another well-established parametric model is denoted as BC (Brooks and Corey, 1964):

$$\begin{aligned} \Theta &= \frac{\theta - \theta_r}{\theta_s - \theta_r} = \left(\frac{\psi_b}{\psi_m} \right)^\lambda & \psi_m > \psi_b \\ \Theta &= 1 & \psi_m \leq \psi_b \end{aligned} \quad (3)$$

where ψ_b is a parameter related to the soil matric potential at air entry (b represents “bubbling pressure”) and λ is related to the soil pore-size distribution. Matric potentials are expressed as positive quantities (i.e., in absolute values) in both the VG and BC parametric expressions. Campbell (1974) proposed a function similar to BC to express degree of saturation ($S = \theta/\theta_s$) in terms of the air entry matric potential ψ_b and an exponent b that can be related to soil texture:

$$\frac{\theta}{\theta_s} = \left(\frac{\psi_b}{\psi_m} \right)^{\frac{1}{b}} \quad (4)$$

ψ_b and b are derived as functions of the geometric mean diameter and geometric standard deviation of the particle-size distribution. Eq. (4) is often used in relation to the fractal idealization of the soil porous system as discussed below.

Estimation of VG or BC parameters from experimental data requires sufficient data points to characterize the shape of the SWC, and a program to perform nonlinear regression. Many computer spreadsheet software packages provide relatively simple and effective mechanisms to perform nonlinear regression. Fig. 4 depicts the parametric VG and BC models fitted to silt loam $\theta(\psi_m)$ data. The resulting best-fit parameters for the VG model are: $\alpha = 0.358 \text{ m}^{-1}$; $n = 1.42$; $\theta_s = 0.418 \text{ m}^3 \text{ m}^{-3}$; and $\theta_r = 0.04 \text{ m}^3 \text{ m}^{-3}$ (with $r^2 = 0.99$). For the BC model, the best-fit parameters are: $\lambda = 0.24$; $\psi_b = 0.79 \text{ m}$; $\theta_s = 0.418 \text{ m}^3 \text{ m}^{-3}$; and $\theta_r = 0.01 \text{ m}^3 \text{ m}^{-3}$ (with $r^2 = 0.98$). Note that the most striking difference between the VG and the BC models is the discontinuity at $\psi = \psi_b$ in the BC model.

The parametric models introduced thus far rely on curve-fitting using parameters related to the specific shape of the employed mathematical function (see Fig. 4) but are not directly derived from the physical characteristics of the soil or other porous media. Certain models have described the relationships between the SWC and the soil pore-size distribution using statistical functions, such as the log-normal distribution used by Kosugi (1994). Conceptually, they represent soil pores as a BCC, whose radii are log-normal distributed and simply apply the capillary-rise equation to establish a relationship between the matric potential and effective medium saturation (see Capillarity chapter). The applicability of these conceptual models is often limited to coarse-textured soils where capillary forces dominate the matric potential and adsorptive forces are negligible (see Water Potential chapter).

SWC parameters

The parameters derived from SWC measurements across different soil types for the VG and BC models are available from a variety of sources. The UNSaturated SOil hydraulic DATABASE (UNSODA) compiled by the US Salinity Laboratory (Nemes et al., 2001)

Fig. 4 The van Genuchten and Brooks and Corey parametric models fitted to measured silt loam SWC data. Some of the most prominent features of the SWC are associated with parameters of these two common models as directly highlighted on the figure.

Table 1 Typical van Genuchten model parameters (α , n) including residual (θ_r) and saturated (θ_s) water contents compiled from the UNSODA database.

Textural class	N	θ_r ($\text{cm}^3\text{cm}^{-3}$)	θ_s ($\text{cm}^3\text{cm}^{-3}$)	α (cm^{-1})	n
Sand	123	0.058	0.37	0.035	3.19
Loamy sand	51	0.074	0.39	0.035	2.39

Silty clay	12	0.163	0.47	0.023	1.39
Clay	25	0.102	0.51	0.021	1.20

N is the number of soils or samples of a given textural class from which the mean values are compiled.

contains an exhaustive collection of soil-water retention and unsaturated hydraulic conductivity information for soils of different textures from around the world. While the authors have attempted to provide some indices concerning quality or reliability of the compiled data, users are advised to use their own experience and discretion when adapting such data to their own applications. Table 1 lists values for the VG parameters α and n , and the residual and saturated water contents for various soil textural classes compiled from UNSODA. Note the large variations in SWC relationships for given soil textural classes. Gutmann and Small (2007) have shown that these variations may exceed differences across soil textures. The origins of these large variations are attributed to lack of consideration of soil structure that may alter SWC parameters for the same soil texture. See Or (2019) for a recent discussion.

Global SWC datasets – from PTFs to CoGTFs

For spatially extensive modeling of hydrologic processes, agroecosystems and land-surface modules of global climate models, soil hydraulic parameterization is an essential input. The present parameterization of soil hydraulic properties is based on detailed maps of soil type and supported by other remotely sensed attributes, using the formalism of pedotransfer functions (PTFs), which primarily use soil information, or covariate-supported geotransfer functions (CoGTFs) that harness numerous other geophysical covariates (vegetation, climate, geomorphic features). The term PTF was coined by Bouma (1989) with the aim of “translating data we have to parameters we need.” Practically, we seek to use a few measured SWC datasets to derive functional relationships with easy-to-measure attributes that are spatially available. These correlations are then used to map the inferred parameters at the desired spatial resolution. The history of regressing easy-to-measure soil attributes for inference of SWC-related parameters dates back the work of Briggs and Lane (1907) and later Veihmeyer and Hendrickson (1927) in the context of deriving plant available water from soil attributes.

We distinguish SWC datasets such as UNSODA (Nemes et al., 2001), HYBRAS (Ottoni et al., 2018), WOSIS (Batjes et al., 2017), AFSPDB (Leenaars et al., 2014) from global maps of SWC parameters. The latter involves the PTF mapping mentioned earlier. Modern SWC parameter maps such as generated with Rosetta 3 (Zhang and Schaap, 2017), HiHydroSoil (de Boer, 2016), CoGTF (Gupta et al., 2021), and the Dai et al. (2019) dataset, provide essential inputs for land surface models. However, these maps suffer from a chronic lack of SWC data, are limited by regional calibration, provide uneven geographical coverage, and yield poorly constrained parameter values. Gutmann and Small (2007) have shown that soil textural classes explain only 5% of the variance of soil hydraulic properties (SHP), suggesting that estimated SHP variations exceed expected differences due to soil texture classification.

A recently compiled Global Soil Hydraulic Properties (GSHP) database (Gupta et al., 2021) encompasses nearly 16,000 well-curated SWC sets spanning 2750 locations globally (as compared with the widely used UNSODA database that contains 218 SWCs primarily from the US and Europe). The CoGTF approach broadens aspects of classical PTFs by using remotely sensed covariates, machine learning, and spatial cross-validation tools to improve training and constraining estimated soil hydraulic parameter values. Table 2 lists mean values for the VG parameters α and n , and the residual and saturated water contents together with their standard deviations for various soil textural classes compiled from the GSHP database.

Physical constraints for SWC parameter estimation

Parameter estimation for the highly nonlinear SWC may result in numerous combinations of parameter sets with similarly good fits to measured data. This nonuniqueness (related to a phenomenon known as sloppy parameter space) may result in combinations of SWC parameters that are not physically consistent. These are identified via SWC-related applications that use the same parameters for example to define the soil unsaturated hydraulic conductivity function, characteristic capillary lengths for different soil types (Lehmann et al., 2008), infiltration behavior at steady state and other physical phenomena that rely on SWC information and its parameters. A potential avenue for identifying unphysical parameter combinations is to use these auxiliary physical phenomena as constraints for SWC parameter estimation (striking a balance between goodness of fit to SWC measurements and ensuring physical consistency) as demonstrated in a study by Lehmann et al. (2020) using a SWC-derived soil trait known as characteristic evaporation length L_c . This is the depth over which capillary flow is maintained and supplies soil water to the soil surface during stage 1 evaporation (when this length is exceeded by a receding drying front, the evaporation plane migrates below the surface giving rise to vapor-transport dominated stage 2 evaporation). The scarce direct measurements of L_c for different soil types (texture classes) have been compiled and are represented (color bars) with the theoretical L_c (black lines) in Fig. 5A from Lehmann et al. (2020). Note that mean theoretical L_c values vary with the underlying parameters deduced from SWC databases (Rosetta 3 or Carsel and Parrish, 1988). As illustrated in Fig. 5B the constrained VG parameter values (red) honor the L_c constraint with minor deviations in terms of goodness of fit.

Tests of the constrained SWC parameters show improved hydrologic performance at small and larger scales. While it is extremely difficult to assess the usefulness of such constrained parameter estimation for the performance of complex models, the approach adds robustness to the estimated parameters at relatively low cost in terms of SWC fit. The concept of injecting physical constraints to SWC parameter estimation can be extended to include other physical constraints for improving PTF estimated SWCs, for example, by consideration of effects on infiltration from vegetation cover and soil structure.

Table 2 Globally-averaged van Genuchten SWC model parameters compiled from the *Global Soil Hydraulic Properties* (GSHP) database.

Textural class	N	θ_r ($m^3 m^{-3}$)		θ_s ($m^3 m^{-3}$)		α (m^{-1})		n (–)

Fractal representation of the soil pore space and the SWC

Fractals are hierarchical, often highly complex, spatial, or temporal systems that are generated with iterative algorithms obeying simple scaling rules (Mandelbrot, 2010). Patterns within such systems repeat themselves over a defined range of scales (self-similarity). This enables the reproduction of statistical properties of a particular pattern at other length or time scales. Fractal geometry can be applied to quantitatively describe irregularity and shape of natural objects by estimating their fractal dimension. Several theoretical models have been proposed to derive the SWC from the fractal representations of the soil porous system (Gimenez et al., 1997). There are two general approaches, based on either surface or mass fractals. Surface fractal models assume that water is only present in the form of adsorbed liquid films on pore surfaces, whereas mass fractal models assume that only capillary water obeying the capillary-rise equation is present within the fractal system. As with the BCC approach, fractal models for the SWC are based on derivation of the pore-size distribution from the fractal structure under consideration, neglecting pore connectivity and topology. Crawford (1994) presented the following relationship between the mass-fractal dimension (D_m) and the degree of saturation (S):

$$s = \left(\frac{\psi_m}{\psi_b} \right)^{(D_m - d_e)} \quad (5)$$

where ψ_m is the matric potential under consideration, ψ_b is the matric potential at the air entry point, and d_e is the embedding dimension. The embedding dimension equals 2 in two-dimensional systems and 3 in three-dimensional space. Note that the mass-fractal dimension D_m is always less than d_e . Because of the identical functional form, Eq. (5) is commonly equated with Campbell's version of the BC SWC function (Eq. 4) to derive Campbell's b -factor from the fractal dimension ($b = -1/(D_m - d_e)$). Fractal approaches are limited due to the assumption that fractal scaling is valid over an infinite range of matric potentials. In reality natural porous media have lower and upper scaling limits related to their minimum and maximum pore sizes.

Physically based SWC models

In contrast to parametric models based on BCC and fractal approaches of soil pores, recent physically based models have adapted a more nuanced representation of soil pores considering angular pores and specific surface area (absent in BCC representation) to simultaneously accommodate capillary and adsorptive phenomena. Despite the unavoidable complexity, the angular pore space model offers several advantages over the BCC approach, including a more realistic representation of natural pores with dual occupancy of wetting and nonwetting phases in the same pores, and accommodation of adsorptive forces for soils with high specific surface areas, which improves SWC representation also under dry conditions.

Tuller et al. (1999) applied the augmented Young-Laplace equation that considers capillary and adsorptive contributions to the matric potential to calculate water-air interfaces within a cross-section of angular pores. This building block and abrupt water displacement mechanisms (snap-off or snap-on) enabled assembly of SWC functions for imbibition and drainage building from pore scale representation. Fig. 6 depicts a typical transition of a unit pore element from dry to wet (imbibition) that includes spontaneous liquid displacement (snap-off) in slits (Fig. 6B) and in the central pore (Fig. 6D). A statistical upscaling scheme using a gamma density function for the central pore length L (Or and Tuller, 1999) enabled transition to the SWC of soil samples.

Fig. 6 Unit element filling stages during imbibition. (A) Liquid films adsorbed on pore and slit walls and liquid held in corners due to capillary forces at low matric potentials; (B) spontaneous slit fill-up (capillary condensation); (C) pore snap-off; (D) full unit element.

Fig. 7 (A) Application of the angular pore-space model for Millville silt loam soil. Note the capillary and absorptive contributions to the soil-water characteristic (SWC); (B) comparison of model-calculated capillary (menisci) and adsorptive (films) contributions to liquid-vapor interfacial area as a function of saturation in an artificial sand mixture and interfacial area measurements obtained with interfacial tracers (Karkare and Fort, 1996; Kim et al., 1997). SA, surface area; M, menisci; F&M, films and menisci. Reproduced from Or D and Tuller M (1999) Liquid retention and interfacial area in variably saturated porous media: Upscaling from single-pore to sample-scale model. *Water Resources Research* 35(12): 3591–3606.

The gamma distribution represents observed soil pore-size distributions and enables analytical expressions for the sample scale SWC. The upscaling procedure represents the degree of saturation (S) as a function of matric potential expressed as the sum of various pore-filling mechanisms as depicted in Fig. 6. Fig. 7A depicts a sample application for Millville silt loam soil. Because the model calculates the configuration of liquid-vapor interfaces within pores and films, adsorptive and capillary contributions to the SWC can be separated (Fig. 7A). Such separation is not possible with any of the empirical or semiempirical approaches presented above. Another important feature of this model is the ability to estimate liquid-vapor interfacial area as shown in Fig. 7B, comparing model estimates for sand with known surface area of $0.01\text{--}0.05\text{ m}^2\text{g}^{-1}$. The magnitude and changes in liquid vapor interfacial area play an important role in multiphase flow processes, bioremediation of contaminated soils, gas-exchange phenomena, and virus and colloid transport.

The complexity of the physical SWC model of Tuller and Or (TO) impeded its practical application. Several simplification have been proposed such as in the work of Lebeau and Konrad (2010), who represented soil pore spaces by combining parallel capillary tubes (similar to the BCC representation) with flat and smooth particle surfaces to facilitate partitioning the SWC into capillary and adsorptive components. Another simplified representation of the TO angular pore model was proposed by Diamantopoulos and Durner (2015). They considered triangular pores for modeling water retention and the effect of the contact angle on water flow to derive closed form expressions for sample-scale liquid retention, hydraulic conductivity, and liquid-vapor interfacial area as a function of the matric potential.

Water adsorption and dry-end SWC relations

Various approaches have been proposed to estimate the dry end of the SWC (e.g., Rossi and Nimmo, 1994; Jensen et al., 2015). These have been based on arbitrary assignment of limiting matric potential values and extrapolation of the water content at these low matric potentials. Here we show that a benefit of the physical representation of the SWC based on the TO model is the simple attribution of adsorptive and capillary components to the matric potential as seen in Fig. 7A. The adsorptive surface forces dominate at the dry end of a SWC (Fig. 7A) where the remaining soil water is held (primarily) in the form of thin liquid films, which gives rise to strong relationship between the dry end soil water content (often referred to as residual water content, θ_r) and soil specific surface area (SA). The dominance of adsorption over capillarity at the SWC dry end greatly simplifies the representation of SWC as demonstrated by Tuller and Or (2005). Considering soil surface-water interactions dominated by van der Waals adsorptive forces, gives rise to a nearly universal scaling relationship for SWC curves at low water contents (Fig. 8A). The relationship can be applied to estimate θ_r [$\text{m}^3 \text{m}^{-3}$] for matric potentials $\psi < -10 \text{ MPa}$ as:

$$\theta_r \cong h \times SA \times \rho_b \quad (6)$$

where SA [$\text{m}^2 \text{kg}^{-1}$] is the soil specific surface area, ρ_b [kg m^{-3}] is the dry soil bulk density, and h [m] is the film thickness as a function of matric potential:

$$h = \sqrt[3]{\frac{A_{svl}}{6\pi\rho_w g \psi}} \quad (7)$$

where A_{svl} [J] is the Hamaker constant for solid-vapor interactions through the intervening liquid, ψ [m] is the matric potential, ρ_w [kg m^{-3}] is the density of the liquid, and g [m s^{-2}] is acceleration due to gravity.

Conversely, the same strong relationship can be applied to deduce soil specific area as illustrated in Tuller and Or (2005) and in several follow up studies (Arthur et al., 2013; Leão and Tuller, 2014). Eq. (8) that relates gravimetric water content θ_m [kg kg^{-1}] to water film thickness and soil specific surface area may be fitted by nonlinear regression to adsorption isotherms measured with the dewpoint hygrometer method (see measurement section below) with SA as a free fitting parameter (Fig. 8B).

$$\theta_m = h \times SA \times \rho_w \quad (8)$$

Table 3 compares the SA obtained by fitting Eq. (8) to water adsorption isotherms measured with the dewpoint hygrometer method and SA measured with the Ethylene Glycol Monoethyl Ether (EGME) adsorption method for a wide range of soil textures and clay mineralogies (Tuller and Or, 2005).

While the SWC dry end is also affected by water held in nano-roughness by capillary forces (that support nanoscale interfacial curvatures), evidence suggests that the contribution to the dry end water content is relatively small and can be combined with surface-area dominated adsorption for many practical applications. However, this does not hold for coarse textured and low surface area soils, where roughness is important.

Pore scale models for realistic pore spaces

With the rapid advancement of computational resources (i.e., high performance computing), several sophisticated simulation techniques including lattice Boltzmann models, smoothed particle hydrodynamics, or volume of fluid methods gained popularity

Fig. 8 (A) SWC curves scaled by soil specific surface area (data are from Campbell and Shiozawa, 1992). The dashed line depicts the adsorption isotherm given in Eq. (7). (B) Eq. (8) fitted to measured data obtained with the WP4C laboratory hygrometer (METER Group, Inc., Pullman, WA, USA). in recent years. Accurate three-dimensional discretization of the soil porous system obtained with X-ray computed micro tomography (μCT), magnetic resonance imaging (MRI), or focused ion beams scanning electron microscopy (FIB-SEM) are used as boundaries for fluid flow simulations (Blunt et al., 2013).

Lattice Boltzmann models (LBM) are descendants of lattice gas cellular automata, which follow the motions of individual particles and were first presented as a viable means of solving Navier–Stokes equations. In the most simplistic sense, LBMs work with distributions of particles at each lattice point rather than with individual particles. LBMs simulate interactions of hypothetical particles confined to a regular lattice, which greatly enhances solvability of the Boltzmann equation. This has advantages for certain types of simulations in that averaging is not required to obtain smooth velocity fields. The lattice Boltzmann method has emerged as a powerful tool for simulation of multiphase fluid systems, including water and water vapor. The LBM incorporates complex details of pore shape that characterize realistic porous media, fluid factors, and solid–fluid interactions in a physically sound way, leading to realistic simulation of interfaces between different fluids or between a liquid and its vapor and adsorption of wetting films. Interfaces arise, deform, and migrate in virtually any pore geometry rather naturally without the need for complex interface tracking algorithms. An example of LBM application to compute water retention in complex porous media is shown in Fig. 9, which is based on two-dimensional (2-D) images of a real soil (Sukop and Or, 2003). Vapor and liquid boundaries of equal pressure were applied to the top and bottom of the domain, respectively, in steps corresponding to equal increments of $\log(-\text{matric potential})$. The matric potential is expressed in mass units per time step squared (equivalent to energy per unit volume in a 3-D system). Each potential step was terminated when the relative change in fluid mass in the domain was negligibly small. The simulated liquid behavior and SWC curve show appreciable differences in fluid configurations during wetting and drying that resulted from hysteresis.

Fig. 9 Lattice Boltzmann model simulation of liquid distribution in a complex pore system and computation of the soil-water characteristic curve. Reproduced from Sukop M and Or D (2003) Lattice Boltzmann method for modeling liquid–vapor interface configurations in porous media. *Water Resources Research* 40(1): W01509.

Smoothed particle hydrodynamics (SPH) was first applied in astrophysics to simulate gas flow dynamics in the course of the fission of protostars. A continuous density field of fluid particles is characterized by a superposition of bell-shaped smoothing functions centered on a set of points. The gradient of the field is represented by the same superposition of the gradients of the smoothing function. A set of properties, such as the particle mass is associated with each particle. The mass can be thought of as being smoothed or smeared by the smoothing function so that the contribution of an individual particle to the fluid density field can be specified and the density field defined (Meakin and Tartakovsky, 2009). The SPH equation for the flow of a perfect fluid is based on the equation of motion $d\bar{v}/dt = -\nabla P/\rho$, where $\bar{v}$ is the local fluid velocity, ∇P the pressure gradient, and ρ the fluid density. The effects of viscosity on fluid flow can be included in SPH simulations by considering the viscous dissipation term in the Navier-Stokes equation. Major advantages of SPH include conservation of mass without the need for further computation (i.e., the particles already represent mass), subtraction of pressure from weighted contributions of neighboring particles rather than by solving linear systems of equations. Furthermore, in contrast to grid-based techniques (e.g., volume of fluid method), which track fluid boundaries, SPH directly creates a free surface for two-phase interacting fluids (i.e., particles represent the denser fluid (water) and empty space represents the lighter fluid (air)). These provisions allow SPH fluid flow simulations in real time.

The volume of fluid method (VOF) provides a powerful, yet efficient means for tracking fluid interfaces (Golparvar et al., 2018). It accurately defines the location and shape of the free surface and simulates its movement during each time step via solution of the Navier-Stokes equation. The VOF method is based on an indicator function (or a set of $n - 1$ functions in the case of n distinct fluid phases), which is advected with the flow. The indicator function is the set of volume fractions within each element of the computational grid (Huang et al., 2005). For air-water interfaces (i.e., in partially saturated soils), the volume fractions for a single phase are sufficient. The effects of surface tension are expressed via a body force that acts on the fluid in cells near (curved) interfaces in which the gradient of the indicator function is non-zero. For multiphase fluid flow in a porous medium, a fluid-fluid-solid contact angle model must be considered in VOF simulations. In summary, while the techniques above are well suited for insights into pore-scale processes, their applicability to sample or profile scales processes is limited.

Pore network models and the SWC

In contrast to the LBM, SPH, and VOF methods, network models consider simple and regular pore geometries (Berkowitz and Ewing, 1998). They were developed based on the idea that pore space may be represented as an interconnected network of capillary tubes whose radii represent the dimensions of the pores within a porous medium. For a given matric potential, liquid-vapor interfacial configurations within the network can be exactly determined, based on pore-scale capillary and dynamic displacement considerations. The macroscopic SWC is then determined based on geometric volume averaging of the spatially distributed liquid within the network. A primary advantage of pore network models is the explicit consideration of pore connectivity and topology in a simplified and mathematically tractable framework. Some of the limitations involve oversimplification of pore-scale physics (e.g., neglect of adsorptive pore-scale processes), incomplete understanding of interface migration and routing, inadequate technologies for inference of network parameters from real samples, and significant computational burden for detailed 3-D networks even at a core scale (greater than 100 mm).

Hysteresis in the SWC

Water content and the potential energy of soil water are not uniquely related, because the amount of water present at a given matric potential is dependent on the pore-size distribution and the properties of air–water–solid interfaces. An SWC relationship may be obtained by: (1) taking an initially saturated sample and applying suction or pressure to desaturate it (desorption), or (2) gradually wetting an initially dry soil (sorption). These two pathways produce curves that in most cases are not identical; the water content of the “drying” curve is higher for a given matric potential than that of the “wetting” branch (Fig. 10A). This phenomenon is called hysteresis, defined as “the phenomenon exhibited by a system in which the reaction of the system to changes is dependent upon its past reactions to change.” The hysteresis in the SWC can be related to several phenomena, including: (1) the “ink bottle” effect, resulting from nonuniformity in shape and sizes of interconnected pores; drainage is governed by the smaller pore radius r , whereas wetting is dependent on the large radius R (Fig. 10B); (2) different liquid–solid contact angles for advancing and receding water menisci (Fig. 10C); (3) entrapped air in a newly wetted soil (e.g., pore doublet); and (4) swelling and shrinking of the soil during wetting and drying. The role of individual factors remains unclear and is subject to ongoing research. Part of the hysteresis phenomena may be attributed to measurement artifacts, for example, due to differences between tension- and pressure-induced desaturation. A potentially important aspect of desorption methods under tension is the possibility of liquid displacement (drainage) even in the absence of a continuous gaseous phase due to cavitation initiated by encapsulated gas bubbles or the liquid’s own vapor pressure. Surface heterogeneity and impurities in soil and rock water are conducive to lowering the cavitation threshold. Also see chapter on Hysteresis.

Fig. 10 (A) Hysteresis of the soil water characteristic. (B) The ink bottle effect and (C) the contact angle effect as potential mechanisms for hysteresis.

Measurement of the SWC

A variety of methods may be used to obtain requisite ψ_m and θ values to estimate the SWC. Potential experimental problems include: the limited functional range of the tensiometer, which is often used for in situ measurements; inaccurate θ measurements in some cases; the difficulty in obtaining undisturbed samples for laboratory determinations; and a slow rate of equilibrium under low matric potential (i.e., dry soils). In situ methods are preferred in defining SWCs, as is measuring over a wide range of ψ_m and θ values. An effective method to obtain simultaneous measurements of ψ_m and θ_v is by installing time-domain reflectometry (TDR) probes in close proximity to transducer tensiometers or more advanced ψ_m sensors (e.g., TEROS 21 sensor, Meter Group, Inc.; Tensiometer sensor, ecoTech Umwelt Meßsysteme) with the attributes monitored during variable soil wetness. Large changes in ψ_m and θ_v are expected under highly evaporative conditions near the soil surface, or in the presence of active plant roots.

Pressure plate apparatus and pressure flow cells

The pressure plate apparatus comprises a pressure chamber that encloses a water-saturated porous plate, which allows water but not air to flow through its pores (Fig. 11A). The porous plate is at atmospheric pressure at the bottom, while the top surface is at the applied pressure of the chamber. Soil samples, usually sieved to less than 2 mm, are placed in retaining rings in contact with the porous plate and allowed to saturate by immersion in water. The porous plate with saturated soil samples is then placed in the chamber and a known N_2 or air gas pressure is applied to force water out of the soil through the plate. Water flows out of the soil until equilibrium between the force exerted by the air pressure and the force by which soil water is being held by the soil (ψ_m) is attained. Soil water retention at the wet end (less than 1 bar) is strongly influenced by the soil structure and its natural pore-size distribution. Hence, “undisturbed” intact soil samples (cores) are preferred over repacked samples for this portion of the SWC. The pressure flow cell (also known as Tempe cell) can hold intact soil samples encased in metal rings (Fig. 11B). The operation of the Tempe cell follows that of the pressure plate, except its pressure range is usually limited to 0–1 bar or 0.1 MPa. The porous ceramic material used in pressure plates and flow cells must be completely water-saturated prior to use. Following equilibrium between soil matric potential ψ_m and the applied air pressure, the soil samples are removed from the apparatus, weighed wet, then oven-dried to determine the mass water content gravimetrically. These may be converted to volume water contents through knowledge of the sample bulk densities. The water content of repacked soils at a given matric potential should not be used to infer θ of intact soils at the same ψ_m , due to modified pore sizes and pore geometry. Multiple pressure steps may be applied to the same soil sample when

Fig. 11 (A) Pressure plate apparatus; and (B) Tempe pressure flow cell used to desaturate soil samples to specified matric potentials.

using Tempe cells. The cells may be sequentially disconnected from the pressure source, weighed to determine the change in water content from the previous step, then reconnected and the next pressure step applied. Outflow of water from the cells may be collected to calculate or confirm changes in sample water contents.

The evaporation method

Another laboratory technique for measurement of the SWC is the so-called evaporation method. It involves evaporation of water from the surface of an initially saturated soil column while concurrently measuring the change in matric potential and the water mass loss. Advanced benchtop evaporation systems such as the HYPROP (METER Group, Inc., Pullman, WA, USA) consist of two miniature transducer tensiometers for matric potential measurements, one installed close to the evaporating surface and the second close to the bottom of the column, and a highly accurate laboratory scale (Fig. 12) that continuously measures the water mass loss. The HYPROP system is fully automated and interfaced with a computer for monitoring the experiment and recording the measurements. From the readings of the 2 tensiometers (kPa), the average matric potential and the hydraulic gradient are calculated.

Fig. 12 State-of-the-art HYPROP benchtop evaporation system (METER Group, Inc., Pullman, WA, USA).

The mass difference, measured with the scale, is used to calculate the volumetric water content and the water flow rate. The experiment is terminated when either one of the tensiometers runs dry or the mass changes become marginal. Then, the remaining moisture content is determined by oven-drying the sample at 105 °C for 24 h. The analytic procedure assumes that the matric potential and water content distribute linearly through the column and that matric potential changes are linear between two evaluation points. The initial water content is determined from the total loss of water (i.e., evaporation and water loss by oven drying). Because HYPROP measurements are limited to the wet end of the SWC due to the functional range of the tensiometers, obtained data are commonly combined with WP4C Dewpoint Hygrometer data for dry conditions (see below). A specifically developed software package allows combining wet- and dry-end measurements and provides means to parameterize the [van Genuchten \(1980\)](#) and [Brooks and Corey \(1964\)](#) SWC models.

Dewpoint hygrometer method

Accurate dry-region SWC data may be measured with hygrometers that rely on the chilled-mirror dew point technique. These instruments measure the relative humidity (RH) in soil air that is considered to be in equilibrium with the soil water phase and convert RH into matric potential with the well-known Kelvin equation assuming negligible osmotic potential. State-of-the-art laboratory hygrometers include the WP4C Dewpoint PotentiaMeter and the fully automated Vapor Sorption Analyzer (VSA) (METER Group, Inc., USA) ([Arthur et al., 2014](#)) (Fig. 13). The WP4C instrument is capable of measuring matric potentials between 1 MPa and 300 MPa. The soil samples need to be brought to different predetermined moisture levels (e.g., 0.01, 0.02, 0.03, 0.04, and 0.05 kg kg⁻¹) and stored in a refrigerator for about 7 days to ensure equilibrium. Once equilibrium is attained, the samples are transferred into WP4C stainless steel sampling cups and soil water potential (matric + osmotic) is measured. Immediately after the measurements the mass of the wet samples is measured. After oven-drying, the exact gravimetric water content of each sample that corresponds to the measured water potential is determined. The VSA is a fully-automated instrument that provides two different isotherm generation modes – the Dynamic Dewpoint Isotherm (DDI) and the Dynamic Vapor Sorption (DVS) methods to measure water vapor adsorption as well as desorption isotherms (+ hysteresis). The VSA dries or wets an initially air-dry (or oven-dry) soil sample and automatically measures the water potential with a chilled-mirror dewpoint technique while simultaneously recording the sample mass throughout the drying or wetting process with a high-precision magnetic balance. Further details regarding measurement technology and procedures and the theoretical basis for subsequent calculations are presented in [Arthur et al. \(2014\)](#).

Paired sensors for field SWC measurement

In spite of the importance of measuring SWCs in situ, few suitable methods are available for field or in situ application. Paired sensors may be used to measure θ and ψ_m in the same or closely adjacent soil volumes, over a range of soil wetness. Examples include the use of neutron moisture meters or TDR sensors, together with tensiometers or more advanced ψ_m sensors (e.g., TEROS 21 sensor, Meter Group, Inc.; Tensiometer sensor, ecoTech Umwelt Meßsysteme). Application of paired sensors is often constrained by differences in soil volumes sampled by the respective sensors, different time constants required (e.g., many θ sensors obtain instantaneous measurements, while ψ_m methods require equilibrium), and the fact that few matric-potential techniques function over the entire range of interest for wetness. This commonly provides limited overlap in soil water retention measured using different techniques, and measurements obtained using different methods may not be consistent in the ranges of overlap.

Abstract

Hydrophobicity ("fear of water") and hydrophilicity ("affinity to water") are qualitative terms that describe the extent of interaction of solid surfaces with water, normally observed in the 3-phase system solid-liquid-air. Hydrophobic dry soil does not imbibe water spontaneously, but rather causes it to ball up and remain at the surface. The water may then penetrate preferentially at other locations, resulting in fast and local movement into deeper layers while leaving dry spots in close proximity. Soil water repellency occurs worldwide and is the cause of many important phenomena like poor water infiltration, heterogenous and fragmented soil moisture patterns, increased overland flow, erosion, reduced irrigation water efficiency and poor plant growth. Due to expected climate change effects, the impact of soil water repellency can be expected to become even more important in the future.

Key points

- Soil water repellency is a decrease in the wetting rate of soil due to its surface properties.
- Extremely water repellent soil has a soil-water contact angle >90 degrees and does not wet. If soils have a contact angle <90 degrees but >0 degree, they are subcritically water repellent.
- Preferential flow paths and dry regions are typical of water repellent soils.
- Water repellency affects erosion, aggregate stability and carbon cycling.

Soil water repellency: How relevant?

Soil water repellency (SWR) was first reported more than 100 years ago, mainly as a rare curiosity associated with specific environments (DeBano, 2000). The early research identified the importance of soil organic matter (SOM) and microorganisms to SWR development, prompting research on how these interactions affect physical, chemical and biological soil processes. As SWR

research increased, its prevalence globally became evident, even in unexpected wet and cool maritime environments. Beyond visually obvious SWR, where water beads on soil surfaces with no infiltration, water infiltration into most soils has been observed to be somewhat influenced by SWR. Soil management and irrigation practices were found to be large drivers of SWR development.

An increase in SWR may cause a substantial reduction in soil water availability, often resulting in poor plant growth and poor irrigation efficiency (Olorunfemi, 2014). Large areas of land can be affected by SWR, such as 2 million ha of agricultural land in South-Western Australia (Blackwell, 2000) alone, where SWR presents a major challenge to agricultural productivity. Nowadays, in conjunction with a still growing world population and increasing demand for food, research to increase soil productivity is important. Worldwide, new trends in agriculture including no-till systems and intensified use of (treated) waste water for irrigation, and the amendment of soil with biochar, manure and other organic compounds have been observed to increase the level of SWR. Recently, further challenges that may exacerbate SWR have emerged. Of particular importance is the recognition of climate change effects, with expected more frequent heavy rainfall and extended water stress periods. In short, SWR may be considered as a feature of many soils that presents a serious threat to a range of ecosystem services.

Examples of processes and phenomena, either initiated or enhanced by SWR, are poor water infiltration, increased overland flow, enhanced wind and water erosion, heterogeneous and fragmented soil moisture patterns, rapid water and solute transport caused by preferential water flow pathways, reduced irrigation water efficiency, poor plant growth and soil carbon sequestration as schematically depicted in Fig. 1.

Few of these SWR-affected processes are represented adequately in recent soil physics textbooks, where it is generally assumed that soils are perfectly wettable. Established and accepted theories based on “classical” capillary concepts like the Richardson-Richards equation for water transport are, strictly speaking, only valid for hydrophilic soils (Or and Tuller, 2022).

This chapter is a continuation of the Chapter “Water Repellent Soils” by Letey (2005), included in the previous edition of the Encyclopedia of Soils in the Environment. The text also refers to various aspects of Or and Tuller’s chapter on “Capillarity” in the present edition. We finally refer to the excellent historical review on more than 100 years of SWR research by DeBano (2000) and the most recent review by Smettem et al. (2021).

Wettability and surface energy

Soil water repellency controls the water dynamics of dry or partly saturated soil (Fig. 2). Instead of immediately infiltrating within seconds, water balls up on the water repellent soil surface. The time it takes for a drop of water to penetrate the soil is a measure of the persistence of SWR, often termed and measured as “water drop penetration time”, WDPT. Additional water at the surface will flow as surface flux to local depressions and may penetrate preferentially along coarse pores or macropores, resulting in fast and preferential flow into deeper layers, while leaving permanently dry spots in close proximity. Extensive infiltration through the entire cross-section does not occur until the water is in contact with the soil for a time equal to or greater than the WDPT, or the water head

Fig. 1 Chemical and physical factors that influence soil water repellency and selected scale-dependent soil processes affected by soil water repellency.

Fig. 2 Water droplets on dry peat. Water balls up and remains at the surface. Photo by S.K. Woche.

Fig. 3 Subcritical water repellent solid surface. The contact angle γ is the angle between the liquid wetting front and the solid surface at the 3-phase contact line and results from equilibrium of the three surface energies: solid-gas σ_{SG} , liquid-gas σ_{LG} , and solid-liquid σ_{SL} . The dashed arrow shows the strain field component caused by the forces at the 3-phase contact line (Good, 1992). Modified from Good RJ (1992) Contact angle, wetting, and adhesion: a critical review. *Journal of Adhesion Science and Technology* 6: 1269–1302.

at the surface becomes greater than the water-entry pressure. Over time, contact between water and soil mineral particles may decrease SWR, with the time taken defined as the persistence of SWR.

The solid-gas surface energy, σ_{SG} , is the fundamental physicochemical property of a solid that governs wettability and capillarity. The expression which connects the surface energies of the solid-liquid-air system with the visible behavior of water, as displayed by the contact angle (CA) visible at the 3-phase boundary line of a water droplet (Fig. 3), was established by Young (1805) and is known as Young's equation.

$$\cos \gamma = \frac{\sigma_{SG} - \sigma_{SL}}{\sigma_{LG}} \quad (1)$$

In Eq. (1) γ is the (intrinsic) CA [°], σ is the surface energy [mJ m⁻²], and the indices S, L, and G denote the solid, liquid, and gas phase, respectively. From Eq. (1) it is evident that wetting of a solid surface by a liquid is controlled by competition between the different surface energies (Fig. 3). For details on the impact of surface roughness and chemical heterogeneity on the CA, we refer to Or and Tuller (2022).

For soil particles, the CA usually varies between 0 degree (completely wettable) and around 140 degrees (extremely water repellent). Soils showing CA >90degrees are usually classified as hydrophobic, whereas soils characterized by CA <90degrees are often referred to as subcritical water repellent (Fig. 4). Zisman (1964) proposed the so-called critical surface energy σ_c of a solid, which equals the σ_{LG} of a liquid showing a zero-degree CA with this solid. The value of σ_c can be determined by measuring CA using a series of liquids with different surface energy. Low solid surface energy σ_{SG} imposes weak attraction between particles and the liquid phase. Generally, pure soil minerals are completely wettable or exhibit small CA due to high-energy surfaces (Lewin et al., 2005). However, soil particles under natural conditions are usually covered by organic substances or mixed with particulate organic matter (Doerr et al., 2000).

Several studies show that SWR is positively correlated with the soil organic carbon content (e.g., Varela et al., 2005). Organic matter usually reduces the particle surface energy, where particularly nonpolar hydrophobic functional groups like —CH₃ likely decrease the wettability and cause hydrophobicity (Tschapek, 1984). This may result in a large number of non-polar sites on the particle surfaces, thick enough to mask the mineral surface properties. The chemical drivers are the amount of hydrophobic —CH groups relative to that of hydrophilic C=O, C—OH, and C—NH₂ groups at the outermost solid-liquid interface of a few Ångström thickness that determine the wettability of SOM (Ferguson and Whitesides, 1992).

Fig. 4 Different wetting regimes are characterized by the relationship between solid-air σ_{SG} and liquid-air σ_{LG} surface energies. The critical surface energy σ_c increased (i) with increasing atomic oxygen (O) concentration and lower carbon (C) concentration and (ii) higher concentration of surface charges.

What makes a soil water repellent?

There are several factors affecting soil wettability (see Fig. 1), the most important of which are briefly discussed below. Soils with high SOM content are usually more likely to develop SWR. The origin of SOM is primarily plant derived organic matter like roots and their exudates, plant tissues and in situ formed pedogenic organic compounds like humic substances. The composition of SOM was found to be more relevant to explain the extent of SWR than the geologic substrate that forms soil minerals. Certain trees, shrubs and grass species are associated with the occurrence of SWR because of the SOM they deposit in soils. Most prevalent are evergreen trees (e.g., *Eucalyptus* spp., *Pinus* spp.) due to the considerable amount of resins, waxes or essential oils they produce in their stems and leaves.

In the soil, various other biological drivers contribute to SWR development. Microbial biofilms and fungal activity create hydrophobic tissues and *exo*-polymeric substances that coat soil minerals and affect soil water characteristics (Doerr et al., 2000). The roots of some plant species exude organic compounds that enhance water affinity and storage capacity above a threshold water content, but switch to water repellency at a lower water content. Hysteretic effects, i.e., differences between the sorption and desorption water retention curves, increase significantly with increasing root exudate concentration (Moradi et al., 2012). Soil moisture dynamics and transport processes at the root-soil interface have become a subject of intensive research (Benard et al., 2018). Numerous studies show a complex modification of physical properties in the rhizosphere compared to surrounding bulk soil.

Due to the wide spectrum and sources of compounds, SWR has been observed for many soils, but it is most prevalent in sandy soils due to the low particle volume to surface ratio and normally uncharged surfaces. In contrast, pedogenic mineral compounds like iron oxides or clay minerals have much greater surface area and usually exhibit charged surfaces or surfaces with functional groups that support wettability, thus reducing SWR. In addition, SWR is often found to be negatively correlated with pH, which is explained by a decreasing polarity of SOM functional groups due to protonation at low pH (de Jonge et al., 1999).

Another factor potentially affecting SWR is the occurrence of wildfires, which are frequently shown to either create or enhance the severity of SWR (Varela et al., 2005), e.g., by reinforcing the bonding of hydrophobic organic molecules to soil particles and chemically intensifying their hydrophobicity by pyrolysis. However, fire-induced reduction and even destruction of SWR in topsoils have also been reported depending on the extent of burning and SOM properties.

However, the modification of water repellency due to environmental processes is a behavior of soil which is still not well understood. To explain changes in wettability as a response to changing physical environmental conditions, Ferguson and Whitesides (1992) proposed a conceptual model of the outermost organic interface, combining theoretical considerations with different experimental methods. They analyzed the wettability of functionalized polyethylene surfaces with several interface-sensitive techniques (CA measurement, X-ray photoelectron spectroscopy, XPS, and attenuated total reflectance Fourier-transform infrared spectroscopy, ATR-FTIR). From this information “interphases” were defined according to the physical depth specifically probed by the different techniques (Fig. 5). The “CA interphase” refers to the outer 0.5–1.0 nm layer whose chemical compounds determines surface wettability. The “XPS interphase” refers to approximately the outer 1–3 nm, the analysis depth of XPS, while the “ATR-FTIR interphase” as the deepest interphase of interest refers to the outer 1 μ m or deeper.

Ferguson and Whitesides (1992) reported that functional groups may still be present close to the CA interphase, but located too deep to influence wetting. They are nonetheless accessible to reagents in solution and able to migrate into the CA interphase, and Ferguson and Whitesides (1992) termed the portion of the interface where this type of interaction is possible as “sub-CA interphase”. The depth of the sub-CA interphase is between that of the XPS and the ATR-FTIR interphase. It is determined by permeability, pore structure, and solid–liquid interactions and is generally less well defined than the depths associated with the respective analytical techniques. This model also explains moisture and temperature affected modification of soil wettability.

Quantification of soil water repellency

Methods based on drop infiltration

It is impossible to measure directly the surface energy of irregularly shaped particles such as soil grains. Therefore, indirect and simple methods based on the penetration behavior of liquids into porous medium of interest were developed (Wallis and Horne, 1992; Letey, 2005). This group of methods includes the water drop penetration time (WDPT) test, the molarity of a water-ethanol droplet (MED) test and numerous subvariants based on the same principle. The WDPT test is the most common method and applied in the laboratory as well as in the field. This test places a drop of water of a controlled volume onto the soil surface and the time required to completely penetrate into the soil is determined. Usually, 5 main WDPT classes are distinguished: non repellent (0–5 s), slightly repellent (5–60 s), strongly repellent (60–600 s), severely repellent (600–3600 s) and extremely repellent (>3600 s) (Dekker and Ritsema, 1994). This test only provides qualitative information, but it is useful to characterize soils with a high degree of water repellency and for in situ investigations under ambient moisture conditions. Over time, the drop of water may transform hydrophobic organic compounds to hydrophilic, so WDPT provides a measurement of SWR persistence.

The MED test is a variant of the WDPT test. It uses water-ethanol mixtures to reduce the surface energy σ_{LG} (i.e., the surface tension) of the solution with increasing ethanol concentration. The 90 degrees-surface tension (σ_{nd}) is the surface tension of the solution where transition from sitting on the surface to penetration occurs. The target value is the ethanol concentration at which the droplet penetrates within 5 s. This concept assumes that a liquid can only penetrate completely and quickly into a porous medium for $\gamma < 90$ degrees.

Theoretical relationships between various surface tensions of liquid and solid and CA have been combined to obtain the following two equations (Letey, 2005):

$$\sigma_{SG} = \sigma_{nd}/4 \quad (2)$$

$$\cos \gamma = (\sigma_{nd}/\sigma_{LG})^{1/2} - 1 \quad (3)$$

Accordingly, the measurement of σ_{nd} can be used to calculate the value of σ_{SG} and γ . It should be noted that the MED test is somewhat unsatisfactory, because of its empirical nature and the lack of a physical foundation (Letey, 2005).

Capillary rise method (CRM) and water entry pressure

The capillary rise method (CRM) can be applied to determine the CA of granular material such as soil particles. Air-dry and sieved (usually <2 mm) material is packed into a tube, which is closed at the lower end with filter paper. The base of the upright tube is brought into contact with a test liquid in a reservoir, and the mass gain of the tube can be recorded with an electronic balance. The maximum height h_m that is reached by the wetting front can be expressed as (Washburn, 1921):

$$h_m = \frac{2\sigma_{LG} \cos \gamma_{st}}{\rho g R_{st}} \quad (4)$$

where h_m is the height of the wetting front above the base of the tube [m], ρ is the density of the liquid [Mg m^{-3}], g is the acceleration due to gravity [m s^{-2}], R_{st} is the mean static radius of pores for an idealized bundle of parallel capillaries [m], and γ_{st} is the static CA [$^\circ$] (Wang and Wallach, 2021). However, reaching equilibrium takes time, often weeks even for small columns. The rate of the rise of the wetting front in the powder-filled glass tube (dh/dt) by means of Poiseuille's law is:

$$w^2 = c \frac{\rho^2 \sigma_{LG} \cos \gamma}{\eta} \quad (5)$$

Eq. (5) suggests a linear relationship between the liquid uptake into the column w^2 and t , with the slope m . This equation cannot be used directly to determine γ , because h is a function of the two unknown parameters R_{st} and γ . This applies to a liquid that partly wets, such as water, as well as to a low surface tension liquid that completely wets the particles, such as *n*-hexane, yielding $\cos \gamma = 1$. The effective pore radius and the CA are not known a priori, therefore *n*-hexane is used as a reference liquid to evaluate first the soil-specific factor c in Eq. (5). Parameter c can be derived from the slope of the function $w^2 = mt$ and the physical properties of *n*-hexane. Once c is known, the capillary rise experiment is carried out with water, from which the CA for water is then determined (Siebold et al., 1997).

A disadvantage of the CRM is that the testing liquid (water or soil solution) does not penetrate for $\gamma > 90$ degrees, which excludes hydrophobic soil from measurement. In this case, a positive pressure, h_p , is needed for penetration and a water head equal to or greater than h_p must exist for water entry. Note that the sign in Eq. (4) changes for $\gamma > 90$ degrees. Measurement of h_p requires an apparatus that allows the height of a water column above the soil to be gradually increased and the ability to determine when the water begins to penetrate the soil. It is interesting to note that the infiltration rate into wettable soils is only slightly affected by the depth of ponded water, whereas infiltration into water-repellent materials is drastically affected by the depth of ponded water h_p .

Repellency index (RI)

An index of SWR can also be determined from the sorptivities of water and ethanol, with the latter being considered as a completely wetting liquid due to its small surface tension. Hexane, as used for CRM, can also be used for these measurements. The water repellency index (RI) compares the infiltration rates of both liquids from a tension infiltrometer, either in the field or the laboratory. Due to ethanol being used as a wetting liquid, MiniDisk infiltrometers (Meter, Pulman, USA) are increasingly used for field studies because they require less liquid than conventional infiltrometers. In the laboratory, small-scale infiltrometers attached to logging balances can obtain measurements of RI at millimeter resolution, such as on the surface of soil aggregates. Common to tension infiltrometers is an ability to control and adjust the tension head of the infiltrating liquid, thereby minimizing macropore flow and allowing for hydraulic conductivity to be measured using multiple tensions. An advantage of the RI approach with infiltrometers is the measurement of intact soil samples, as abrasion from sieving affects SWR. However, the approach does not provide a direct measurement of CA and the shape of the wetting front in hydrophobic soils may affect measurements. Disadvantages described above for CRM also apply. For further details see Olorunfemi (2014).

Sessile drop method (SDM)

The sessile drop method (SDM) measures the CA of a sessile drop on soil minerals directly using a goniometer fitted microscope. Advanced devices use video recording and computer-aided CA evaluation of the drop contour as shown schematically in Fig. 3. The measurement is static, taken immediately after placing the drop onto the sample, but it can also be made dynamically (i.e., advancing and receding CA mode) by adding or removing liquid from the drop during the measurement or by tilting the sample. Soil samples are usually prepared by pressing a one-grain layer of dry soil particles onto a glass slide covered by double-sided adhesive tape (Bachmann et al., 2000). The initial CA is evaluated immediately after placing a small drop of water (e.g. 1 μL). An advantage of the SDM is that different liquids may be used to evaluate both wettability and surface energy components of soil particles (see Eq. 8). It should be noted that the sessile drop CA, in the strict sense, does not allow for the derivation of exact thermodynamically valid data because soil particle surfaces are rough, heterogeneous, anisotropic, elastic, deformable, and may react with the wetting liquid (Drehlich et al., 2019). Nevertheless, the derived values are useful approximations, which can be applied for many research questions.

Wilhelmy plate method (WPM)

This method is based on a procedure originally proposed by Wilhelmy (1863). A solid body that is partly immersed into a liquid is subject to at least three different forces: the gravity force which acts vertically downward, the buoyancy force which acts vertically upward and the interfacial menisci forces at the 3-phase contact line around the body. In the original setup, a platinum plate is connected with a balance and then lowered into a reservoir filled with a test liquid, providing a measurement of surface tension, assuming a zero CA of the plate. The principle has been inverted for soil studies, by using a liquid with a known σ_{LG} (e.g., water) to evaluate the unknown CA (Bachmann et al., 2003). A small glass slide, with adhesive tape and a one-grain layer of soil particles on

all sides can be used. The buoyancy force F_b increases linearly with the plate's depth of immersion. At any stage, while the plate is partly immersed, the total force F_t that is acting on the plate can be given as:

$$F_t = W - F_b - F_w = W - V\rho g + l_w\sigma_{LG}\cos\gamma \quad (6)$$

The symbol W [kg] in Eq. (6) denotes the mass of the sample, V [m³] is the volume of the immersed part of the sample, and l_w [m] is the wetted length of the sample. The CA can be calculated by:

$$\cos\gamma = \frac{(F_t + V\rho g)}{l_w\sigma_{LG}} \quad (7)$$

One advantage of the WPM is that it covers the entire CA range between 0 and 180 degrees and, depending on the immersion dynamics and direction (into or out of the liquid reservoir), allows for the measurement of dynamic advancing and receding CA, similar to SDM. Due to the physical principle applied, advancing CA measured with WPM are larger and receding CA smaller than corresponding static CA measured with SDM.

Surface free energy components

Based on CA data it is possible to determine polar and non-polar surface free energy components. These components are, for instance, important to predict interactions between colloidal particles (e.g., clay minerals and bacterial cells) and soil pore surfaces in aqueous media (Bos et al., 1999). The relevant surface energy components of colloids and adsorbing surfaces can be determined experimentally using the van Oss-Chaudhury-Good Eq. (8) (van Oss et al., 1988):

$$(1 + \cos\gamma)\sigma_{LG} = 2\left(\sqrt{\sigma_{SG}^{LW}\sigma_{LG}^{LW}} + \sqrt{\sigma_{SG}^{+}\sigma_{LG}^{-}} + \sqrt{\sigma_{SG}^{-}\sigma_{LG}^{+}}\right) \quad (8)$$

The superscripts 'LW', '+', and '-' denote the non-polar Lifshitz-van der Waals component, the electron-acceptor (acid) component, and the electron-donor (base) component, respectively. To determine the three unknown variables, σ_{SG}^{LW} , σ_{SG}^{+} , σ_{SG}^{-} , in Eq. (8), the solution of a system of three independent linear equations is needed. This can be achieved by measuring CA using three different liquids (with two of them being polar) with known surface energy components, e.g. deionized water, ethylene glycol, and α -bromonaphthalene.

Soil processes affected by water repellency

Water repellency is an important controlling factor of soil hydraulic processes and affects potentially all processes in the soil where water is involved. SWR can have significant effects on water infiltration, water storage, solute transport in the unsaturated zone, soil water balance, surface runoff and soil erosion, soil fertility, irrigation efficiency, aggregate stability and the protection of SOM against microbial degradation. Not all of these SWR impacts are negative. Small levels of SWR, previously described as subcritical, may enhance aggregate stability and the physical protection of SOM. It is evident that SWR has important repercussions on different spatial scales, ranging from the landscape to the pore scale.

Infiltration and preferential flow

If one imagines a strong precipitation event occurring after a long drought period with precipitation falling on a dry water repellent soil surface, the immediate effects of SWR on soil hydrology become intuitively conceivable. At the onset of such an event, infiltration will be considerably reduced and precipitation may pond or run-off the soil surface, with a variable portion eventually infiltrating via preferential flow paths into the soil. The initial effect of SWR leads to a different partitioning of precipitation, decreasing the amount infiltrating water and increasing the amount of run-off water. The impact of SWR can be very pronounced, as demonstrated in a study by Lemmnitz et al. (2008), where the fraction of surface run-off for a subcritically water repellent plot (CA $\approx$ 45 degrees) was found to be 96.4% as compared to 11.4% for a completely wettable plot that received the same amount of precipitation.

Infiltration into a water repellent bulk soil matrix will usually not occur until water has been in contact with the soil surface for a time equal to or greater than the WDPT, corresponding to a CA < 90 degrees. The degree of repellency usually reduces with time after contact with water (Wang and Wallach, 2021), which explains the typically observed increase in infiltration rate with ongoing precipitation. In flat or gently sloping terrain, where run-off flow is typically small and water may pond on the water repellent soil surface, infiltration can also be initiated when the depth of the water layer at the surface is greater than the water-entry pressure. The special features of water repellent soils are clearly reflected in their infiltration dynamics. While a wettable soil is typically characterized by a fast initial infiltration rate, which decreases and eventually becomes relatively constant with time when sufficient water is available at the surface, the rate of infiltration into a water repellent soil is slow during the initial phase of infiltration and increases with time (Fig. 6).

Fig. 6 Typical infiltration curves of a water repellent and a wettable soil. Figure redrawn from Letey J, Osborn J, Pelishek RE (1962) The influence of the water–solid contact angle on water movement in soil. *International Association of Scientific Hydrology Bulletin* 7: 75–81.

If the water infiltrates through preferential flow paths into the subsoil it will by-pass large domains of the topsoil, which can lead to dry surface soil and greater moisture content in the subsoil. In general, preferential flow effects triggered by SWR can cause partitioning of infiltrating water, potentially leading to the formation of wet and dry domains in close proximity, where differences in volumetric water content can reach more than 35% (e.g. Dekker and Ritsema, 1995). These domains can be stable for months. Water repellent properties can induce very high levels of small (mm)-scale variability in soil water movement (Hallett et al., 2004), but the exclusion of water from water repellent soil domains can also be effective at a larger (m)-scale (Oostindie et al., 2008).

As SWR is strongly dependent on SOM content, it is usually mostly pronounced in topsoils. The effects of SWR-induced preferential flow therefore typically decrease with depth, frequently leading to a more homogeneous moisture distribution in the deeper subsoil. But SWR has also been found to increase with depth, exerting a strongly significant impact on soil moisture distribution and water movement in the deeper subsoil. Even if a subsoil is completely wettable, the preferential flow phenomena, once initiated in the topsoil or in the organic layer, may also be effective at deeper depths. For instance, in a sloped forest soil Gerke et al. (2015) observed surface run-off underneath an organic topsoil (biomat) layer caused by a water repellent A horizon. From the analysis of the staining pattern after irrigation (Fig. 7), they concluded that the biomat layer and mineral soil surface topography generated locally preferential flow pathways in deeper mineral soil layers instead of homogeneous infiltration into the wettable mineral soil.

However, these phenomena are not restricted to hillslopes, but can also be found in flat terrain, as visualized by the preferential infiltration pattern found for a loamy sandy beech forest site, reaching depths of more than 130 cm in the wettable subsoil (Fig. 8). For a more quantitative discussion on the mechanisms causing preferential flow phenomena we refer to Letey (2005) and Hendrickx et al. (1993).

Microscale water configuration

SWR may also have important repercussion on the microscale (pore or particle scale) distribution and continuity of the liquid phase in the soil matrix. Microscopic water distribution in the wetted pore system of a water-repellent soil can differ strongly from a wettable soil at the same soil water content (Muehl et al., 2012). Environmental scanning electron micrographs have revealed pronounced differences in the microscale water configuration on subcritically water repellent ($CA \approx 50$ degrees) and strongly

Fig. 7 Schematic representation of water meniscus entering an air-wet pore throat. Negative values are for water infiltration with $CA < 90$ degrees, positive values for $CA > 90$ degrees, as indicated by the height of the water level. Consequences are surface run-off generation and local infiltration into the hydrophobic mineral topsoil layer. Figures redrawn after Gerke KM, Sidle RC, Mallants D (2015) Preferential flow mechanisms identified from staining experiments in forested hillslopes. *Hydrological Processes* **29**, 4562–4578.

Fig. 8 Moisture distribution 24 h after infiltration with “Brilliant Blue” (irrigation rate 22 mm/h, total amount 200 mm). The testing site is a 100 year beech stand on loamy sand. Organic top layer and topsoil were rated as hydrophobic ($CA > 90$ degrees). Zones of preferential water flow are clearly indicated by dyed areas. Formation of corresponding flow pathways accelerate water and solute transport into ground water and reduces plant available water.

hydrophobic ($CA \approx 160$ degrees) particles (Goebel et al., 2011). While slightly water repellent particles were wetted uniformly, promoting good water connectivity between the particles, water formed small droplets on the hydrophobic particles, resulting in greatly reduced water connectivity between individual particles, confined by the diameter of the water drops formed between them. In addition, water film thickness on particle surfaces can be strongly affected by particle wettability. It has been shown that water film thickness on slightly water repellent quartz particles ($CA = 10$ degrees) is reduced by a factor of 5 as compared to completely wettable quartz particles (Chruaev, 2000), showing that already small differences in wettability can have a strong impact on water film thickness.

Evaporation

The development of a water repellent surface layer can also reduce subsequent drying of deeper soil layers by preventing evaporation and upward capillary movement of water. The effectiveness of SWR to reduce evaporation seems to be more affected by the location (depth) of the water repellent layer within the soil profile than by its thickness (Shokri et al., 2008). The reduction in evaporation in the presence of a water repellent layer is usually explained by the interruption of capillary flow, suggesting that the flux across the water repellent layer is purely diffusive. However, investigations with mixtures of hydrophilic and hydrophobic sand grains revealed gradually decreasing evaporation with an increasing fraction of hydrophobic grains (Shokri et al., 2009). This suggests that the primary mechanism for the reduction in evaporation is not necessarily a complete interruption of capillary flow but rather a reduction in capillary driving forces.

Indirect effects of soil water repellency

Aggregate stability

Several studies have shown that increasing SWR favors the stability of soil aggregates. The protection of aggregates due to SWR is mainly related to the reduction of the initial wetting rate, which diminishes the build-up of air-pressure in soil pores, thus reducing the slaking stress. A decrease in aggregate stability is often accompanied by a decrease in hydrophobic organic matter compounds, such as lipids. The important role of hydrophobic organic compounds was demonstrated by [Piccolo and Mbagwu \(1999\)](#), showing that aggregate stability markedly increased after the application of hydrophobic substances. The particular role of SOM in stabilizing soil aggregates is not only caused by its effect on SWR but also due to mechanical stabilization mechanisms (e.g. by enmeshment of mineral particles), which often makes it difficult to clearly differentiate the effects of SWR on aggregate stability. However, [Mataix-Solera and Doerr \(2004\)](#), for instance, could demonstrate for soils with similar organic carbon contents that aggregate stability is clearly enhanced with increasing SWR. [Goebel et al. \(2005\)](#) showed that a CA difference of only 13 degrees can significantly reduce water uptake rates and enhance aggregate stability of air-dry aggregates immersed in water, concluding that wettability is a better predictor of the initial aggregate breakdown dynamics than the total amount of organic carbon, particularly at very low organic carbon contents.

Erosion

Because of their reduced infiltration capacity, water repellent soils have often been associated with the occurrence of soil erosion, and several authors found a positive relationship between the degree of SWR and the amount of soil mass displaced by erosion ([Shakesby et al., 2000](#)). Particularly, in coarse-textured soils or soils with low organic matter content, SWR can strongly enhance erosional processes. For instance, in a study on a loamy sand soil, [Bodí et al. \(2012\)](#) found a more than 20-fold increase in sediment yield when hydrophobic (WDPT >3600 s) compared to the wettable counterpart (WDPT = 0 s). For soil erosion it is often difficult to differentiate the effects of SWR from other co-varying factors. In particular, the existence or lack of a vegetation and litter cover strongly affects whether SWR will have an effect on soil erosion. In this context, the spatial distribution of SWR can also be important for its potential to induce soil erosion, meaning that although SWR can induce high runoff locally, the effects at larger scales can be strongly attenuated ([Coelho et al., 2004](#)). Likewise, an enhanced aggregate stability often found in water repellent soil can increase the resistance to erosion.

Microbial activity and carbon sequestration

In contrast to wettable soils, water repellent soils are often characterized by less available water, which in turn is often more heterogeneously distributed in the soil matrix, leading to the formation of persisting dry domains. Soil microbial activity is strongly governed by the availability of water, so it can be reduced or even completely absent in such dry soil domains, meaning that residing SOM may be effectively protected. Beyond these effects, which are generally relevant at the profile scale, the previously described impact of SWR on water film thickness and continuity (heterogeneity) can have a strong impact on microbial activity. As shown by [Or et al. \(2007\)](#), diffusion rates of extracellular enzymes to SOM and of dissolved substrates back to the microbial cells are proportional to the thickness of the water film surrounding soil particles. The reduction in diffusion can result in a physical separation of microorganisms from substrates and nutrients and may cause dormancy and long-term starvation ([Kieft et al., 1993](#)). In summary, SWR can contribute to the formation of biologically non-preferred soil domains at different spatial scales, where microbial decomposition processes are reduced or even temporarily interrupted.

Plant growth

SWR-induced reduction in water infiltration and formation of preferential flow paths can significantly affect soil water recharge and the amount of plant-available water in deeper soil layers ([Lozano-Parra et al., 2016](#)), with important effects on irrigation efficiency ([Olorunfemi, 2014](#)). A study by [Ursino and Rulli \(2010\)](#), investigating the effect of water availability on vegetation patterns, suggested that post-fire vegetation patterns can be significantly affected by SWR. In this context, it is important to note that a change in vegetation structure may have substantial consequences for SWR itself, because increasing soil dryness can favor drought resistant vegetation, whose litter is typically rich in oils and waxes ([Doerr et al., 2000](#)). Over the long-term, this can further enhance SWR.

Moisture-affected dynamics of soil water repellency

Wetting of water repellent soil is governed by at least two mechanisms. First, increasing moisture content decreases the CA. This arises because already wetted surfaces (water menisci or water-film coated soil particles) exhibit a zero-CA to the contact area of a water drop placed onto the moist surface. Hence, the observed CA is a mixed signal resulting from the fractional area of either water repellent (grain) or wettable (water) surfaces, according to the Cassie-Baxter composite surface model ([Or and Tuller, 2022](#)). Secondly, beside the “pure” water content effect, a reorganization of the molecular structure at the solid interfaces in contact with water takes place (see [Fig. 4](#)).

During rainfall the wetting resistance of the soil surface can be reduced when the volumetric water content θ reaches a threshold, called the critical water content θ_{crit} ([Dekker and Ritsema, 1994](#)). Values of θ_{crit} can range from 2% by volume for a dune sand to about 40% by volume for a SOM-rich silt loam soil. [Fig. 9](#) shows soil wettability in terms of CA as a function of θ and capillary

Fig. 9 Schematic diagram showing the initial SDM CA as a function of volumetric water content θ (left) and the pF-value (right). Area under the curve ($S_{WR(\theta)}$), the θ at the maximum SWR (θ_{WR-max}), the θ where SWR ceased (θ_{non-WR}), the maximum CA ($CA_{i,max}$), the pF at the maximum SWR (pF_{WR-max}) and the pF where SWR ceased (pF_{non-WR}). Figure taken from Wijewardana NS, Müller K, Moldrup P, Clothier B, Komatsu T, Hiradate S, de Jonge LW, Kawamoto K (2016) Soil-water repellency characteristic curves for soil profiles with organic carbon gradients. *Geoderma* **264**: 150–159.

Fig. 10 Initial sessile drop CA for Ah horizons of sandy beach forest soils initially treated at 20, 40, and 80 °C. Letter 'A' stands for normal air-drying after water addition, 'N' means shock-freezing of wet soil material with subsequent freeze-drying. Repeated letters mean a series of treatments, e.g., A_A_N denotes repeated air-drying, rewetting and finally shock-freezing. Figure by S.K. Woche.

pressure (pF values) over a wide moisture range. It shows a decrease in CA at pF values larger than permanent wilting point ($>pF\ 4.2$) and a CA maximum at pF 4.2, which might be explained by reduced surface energy due to adsorbed water vapor as reported by Goebel et al. (2004). The CA-decrease at higher moisture contents could be caused by the formation of water films and water menisci as discussed above.

Structural reorganization of the multi-component interface, either caused by contact with water or by temperature, is shown in Fig. 10. Both treatments affect the wetting properties in the CA-sensitive interphase (see Fig. 5), which is a reversible process.

Displayed for each variant are the mean CA of five forest soils ($n = 50$) after the first wetting–drying cycle (A = air-drying after wetting, N = shock-freezing in liquid N₂ and freeze-drying after wetting) and after three repeated wetting–drying cycles, with finally a reversed drying procedure (A_A_N). Initial CA were similar for the 20 °C and 40 °C pretreatment before wetting–drying cycles followed, while samples pretreated at 80 °C had a higher CA level for the initial treatment and the following cycles. Air-drying always led to larger CA than shock-freezing/freeze-drying. Dynamic CA fluctuations reflect temperature and wetting effects in accordance with the interface model shown in Fig. 5. Recently, Woche et al. (2017) confirmed a close connection between the molecular setup in the outermost interface of soil particles by comparing XPS data to determine surface chemical composition with sessile drop CA to quantify the degree of SWR. Finally, Bachmann et al. (2021) concluded that shock-freezing/freeze-drying allows a direct access to the ambient wetting properties of the solid–water interface which might support the next steps in hydraulic model development.

Modelling

Hydraulic models of SWR are being developed from phenomenological approaches (Dekker and Ritsema, 1994), complex models based on the Richardson-Richards equation (Deurer and Bachmann, 2007) or pore-scale modelling in the rhizosphere (Benard et al., 2018). Model calculations based on the Lattice-Boltzmann simulation technique have shown a good agreement between pore-scale simulations of a sessile drop CA (Kang et al., 2018) and common approaches to account for the effect of roughness (Wenzel effect) and chemically composite surfaces (Cassie-Baxter effect; Bachmann and McHale, 2009). It is essential to unravel the question of when SWR will occur or disappear and the governing factors for dynamically changing wettability. Mao et al. (2019) discussed in their review paper possible mechanisms for the occurrence and persistence of SWR from nano to ecosystem scale. They

concluded that understanding the molecular setup at soil particle surfaces is essential to understand SWR as the basis for various model concepts able to distinguish clearly between processes occurring in wettable and water repellent soil.

Dealing with soil water repellency

Different techniques have been developed to mitigate the effects of SWR. Wetting agents are the most effective method to reduce or eliminate SWR, at least for some time. Generally, wetting agents are differentiated into three classes of surfactants, i.e. nonionic surfactants, anionic surfactants and block polymer nonionic surfactants, whereas nonionic surfactants are most widely used in agricultural production (Olorunfemi, 2014). Several mechanisms are associated with surfactants. The surfactant lowers the surface tension of the water, which reduces the solid-liquid CA, i.e., the soil becomes more wettable (Letey, 2005). In turn, reducing the surface tension of water may lower the capillary forces, which potentially decrease the infiltration rate when the soil is wettable or only slightly water repellent. Further, surfactant molecules are adsorbed by the soil as the solution moves downward.

Surfactants generally have a molecular structure consisting of a polar (hydrophilic) end and a non-polar (hydrophobic) end. In the soil, the hydrophobic end adsorbs to water repellent coatings via hydrophobic adsorption mechanisms, whereas the hydrophilic part of the molecule remains at the coating surface. Adsorption of the surfactant molecule converts a water-repellent soil to a wettable soil upon drying. However, as the surfactant is adsorbed from the solution, the surface tension of the solution increases again and wettability decreases. Therefore, surfactants are most effective in treating SWR when it is associated with the surface layer of the soil (Letey, 2005). Converting the uppermost soil layer to a wettable one, e.g. by surfactants, acts as if the level of water ponding is increasing with the depth of the wettable layer, which improves infiltration into deeper, still repellent layers. Although wetting agents are effective in improving water infiltration, they are expensive and only temporarily effective. Therefore, surfactants are most commonly applied in highly managed golf course soils, but their use in agriculture is increasing, particularly for higher value horticulture.

Mitigating SWR includes watering practices to keep the water content above the critical value and to reduce water loss due to evaporation, i.e., via mulch layers on the soil surface. Furthermore, tillage may lead to abrasion of hydrophobic organic coatings and might improve wettability, as can adding hydrophilic clay into the surface layer of a water-repellent sand. Conversely, shifts to reduced tillage may decrease severe soil water repellency because of the impacts to soil biology and organic matter decomposition dynamics. An extended overview on this topic is provided by Ritsema and Dekker (2003).

Conclusions and outlook

Soil water repellency has been described for decades. It can be considered as a phenomenon that occurs worldwide and may affect specifically different ecosystem service functions, depending on the respective land use system and climatic conditions. A challenge of current SWR research is to finally develop a mechanistic understanding of bio-physical interactions, including models and concepts that are consistent on all spatial scales of interest, from catchment hydrology down to particle interfaces. With climate change and the increased use of greywater for irrigation, the prevalence of SWR and its impacts, can be expected to worsen over time.

Abstract

Soil aeration affects plant growth, nutrient cycling, greenhouse gas emissions, soil remediation, and soil morphology. In a general sense, soil aeration is the interchange of gases between the atmosphere and the earth, but often refers more specifically to oxygen status which is largely affected by respiration of plant roots and soil microbes. Soil-atmosphere exchange of gases also results from other biogeochemical reactions that consume or produce gases and physical processes of diffusion and convection which are influenced by soil texture, structure, water content, and temperature. This chapter provides an overview of the key processes affecting and affected by soil aeration.

Key points

- Soil aeration influences soil fertility and plant growth and also affects numerous biochemical processes that have diverse ecological impacts.
- 'Aeration' may refer to a wide range of gaseous species that can be present in soil or may be used more specifically to refer to oxygen status.
- Soil-atmosphere gas exchange results from biogeochemical reactions that consume or produce gas concentration gradients that drive diffusion.
- Gas transport processes are influenced by soil physical properties including texture, structure, water content and temperature.
- Dissolved gases play a critical role in regulating soil microbial and chemical activities.
- This chapter provides an overview of the key processes affecting and affected by soil aeration.

Introduction

Soil aeration status is a critical factor influencing soil fertility and plant growth (Ben-Noah and Friedman, 2018) and affecting numerous soil biochemical processes. Many of the soil processes affected by aeration status have important, and diverse, ecological impacts including, but not limited to, greenhouse gas emissions (Wang et al., 2021), tropospheric ozone (O₃) production (Lu et al., 2021), stratospheric O₃ depletion (Ravishankara et al., 2009), and mercury speciation (Xu et al., 2019). Aeration is also an important factor in remediation of contaminated soil (Fragkou et al., 2021). Over decadal or longer time scales, aeration also impacts soil genesis and morphology which can impact shorter-term processes such as nutrient cycling (Gasparatos et al., 2019).

In a general sense, aeration is the interchange of gases between the atmosphere and the earth, and the term 'aeration' may be used in referring to a wide range of gaseous species that can be present, and move in or out, of soil. Gases expected to be present in soil air include not only those that predominate in earth's lower atmosphere, i.e., dinitrogen (N₂), oxygen (O₂) and argon, but a range of

Fig. 1 Schematic diagram indicating the general flow directions of important gases within soil.

other 'biogenic' gases produced by microbial and plant processes within soil which are present in much greater concentrations than in the atmosphere. Thus, one way to characterize a soil's aeration status is by comparing the composition and concentrations of the gases in soil pores to that of the above-ground atmosphere (Fig. 1).

In soil, we are often concerned with O_2 status because it has a critical impact on a range of biological processes, both plant and microbial. In general, O_2 moves from the atmosphere into soil and is consumed by respiration which in turn results in the production of carbon dioxide (CO_2). Thus, soil O_2 and CO_2 concentrations often trend in opposite directions relative to atmospheric levels. In addition to respiration, other microbiological processes including decomposition, nitrification, and denitrification, as well as chemical reduction/oxidation reactions can also affect, and be affected by, soil aeration status. When O_2 becomes depleted, this can alter some of predominant biochemical and chemical processes and pathways and this may in turn alter the production of other gases. For this reason, O_2 can be considered as a 'master regulator' of soil biochemistry and therefore the term 'aeration' is often used specifically to refer to a soil's O_2 status.

The production or consumption of O_2 , CO_2 and other gases in soil creates concentration gradients that drive gas movement via diffusion within the soil and flux across the soil-atmosphere interface. Pressure gradients arising from natural barometric variations or from incorporated materials may also drive gas movement via convection. The physical processes of diffusion and convection are influenced by soil physical properties including texture, structure, water content and temperature. Human activities can result in the accidental or intentional introduction of gases in the soil profile such as fumigants, anhydrous ammonia, pesticides, and various organic chemical contaminants, for example, gasoline constituents with high vapor pressures such as benzene, toluene and xylene (Rolston, 2002), which can also create concentration and pressure gradients that drive soil gas exchange.

This chapter provides an overview of the key processes affecting and affected by soil aeration. Soil aeration has been reviewed previously with a focus on aeration as it relates to plants (Glinski and Stepniewski, 1985) and more recently by Ben-Noah and Friedman (2018). The early 20th century assessment of soil aeration by Russell and Appleyard (1915) also provides valuable historical context for the role of aeration in relation to soil biological processes. These references and others cited below are recommended as additional references.

Soil air content and composition

Soil is a multi-phase system comprised of varying proportions of gas, liquid and solid materials. Therefore, the relative proportions of each of these phases are important properties representing the state of the soil system at a given time and location. The term 'soil air' is often used to refer to the soil gas phase, although the composition of soil gas is often much different than what is normally referred to as atmospheric 'air.' The relative amount of air contained in a soil on a volume basis, or the soil-air content (ϵ , $m^3 \text{ air } m^{-3} \text{ soil}$), is directly related to its bulk density (ρ , $Mg \text{ soil } m^{-3} \text{ soil}$) and volumetric water content (θ , $m^3 \text{ H}_2\text{O } m^{-3} \text{ soil}$). To estimate ϵ under a given set of conditions, the soil's total porosity (ϕ), which may be occupied by water and air in different proportions, is first determined from $\phi = 1 - \frac{\rho}{\rho_p}$, where ρ_p is the particle density generally assumed to be $2.65 \text{ Mg } m^{-3}$ for mineral soils (Jury and Horton, 2004). This allows the determination of ϵ from $\epsilon = \phi - \theta$. Since ρ of natural soil varies from approximately $1.0 \text{ Mg } m^{-3}$ to $1.8 \text{ Mg } m^{-3}$, ϕ varies between 0.3 and 0.6, meaning that the total pore space represents 30–60% of the total soil volume. Thus, under dry soil conditions, ϵ can vary over this same range, but will decrease below this range as soil-water content increases. Another index that is often used as an indicator of soil-water content, and as a proxy for soil aeration status, is water-filled pore space (WFPS) which represents the fraction, or percentage, of the total pore space occupied by water, calculated from $\frac{\theta}{\phi}$ (Linn and Doran, 1984). This calculation can also be convenient for expressing soil-air content where the percentage of the total pore space occupied by air, or air-filled pore space (%AFPS) is given by $100 - \%WFPS$ or $100 (1 - \frac{\theta}{\phi})$. These relationships can be used to determine, for example, in a soil with $\rho = 1.2 \text{ Mg } m^{-3}$, the pore space would be equally occupied by water and air ($WFPS = AFPS = 50\%$) when $\theta = 0.274$.

The composition of soil air depends on the relative magnitude of the sources and sinks of the various gas components and on the rate of interchange between soil air and atmospheric air. If a soil were completely 'aerated' the concentrations of gases in soil air would be similar to that in the atmosphere. Under most conditions, O_2 concentrations in soil air will be somewhat below that in the ambient atmosphere ($\sim 20\%$ by volume) while CO_2 concentrations will be relatively elevated.

Under some conditions, O_2 concentrations can be completely depleted. Conditions where O_2 is absent are referred to as 'anoxic' and processes taking place in the absence of oxygen are commonly referred to as 'anaerobic' processes. Under many conditions, soil

profiles are neither fully aerated nor fully anoxic but are somewhere between these extremes (Scott, 2000). In addition to being needed to estimate the soil-air content, different indices of soil-water content (e.g., WPFS) are often used as proxies for O₂ availability because it is often difficult to directly measure soil O₂ concentrations.

The major constituent of the atmosphere (N₂) does have both a biological sink (biological N fixation) and source (denitrification) in soil. However, due to its high background concentration in the atmosphere (~78%), N₂ concentrations in soil air are particularly difficult to measure. Methods to determine soil air N₂ concentrations or rates of soil-to-atmosphere N₂ flux driven by denitrification have been developed (Yang and Silver, 2012; Butterbach-Bahl et al., 2002; Burgin and Groffman, 2012). Earlier studies have detected substantial variation in N₂ concentrations that appeared to be affected by rainfall events that may have trapped gases rising from below, dissolved or displaced N₂ in the soil air (Hinkle, 1994).

Among the biogenic trace gases, CO₂ concentrations in soil air can be as high as 10–40 times that in the atmosphere (Chen et al., 2005) which is currently 412 ppm or 0.0412% by volume. Depending on the particular soil system and its land use, the soil air is also expected to contain varying amounts of other gases including ammonia (NH₃), nitric oxide (NO), nitrous oxide (N₂O), nitrous acid (HONO), methane (CH₄), hydrogen sulfide (H₂S), and ethylene (C₂H₄) all of which may be present in amounts that far exceed their concentrations in the atmosphere. These gases result from numerous microbial or plant processes that cannot be fully reviewed here but are covered to some degree in later sections.

Another important difference between the above-ground atmosphere and soil air is that relative humidity in soil air rarely drops below 90% due to the presence of strong capillary and adhesive forces between soil surfaces and water molecules (Or et al., 2004), whereas in the atmosphere, relative humidity varies over a much broader range. One consequence is that water vapor concentrations in soil air are commonly in the range of 1–5% by volume, which is generally greater than or similar to concentrations of biogenic gases such as CO₂, CH₄ and N₂O. This can complicate the quantification and characterization of soil air chemical composition, depending on whether or not water vapor concentrations are taken into account. Water vapor transport in soil and across the soil-atmosphere interface can also contribute to convective movement of soil air in complex ways due to its coupling with energy and liquid water fluxes (Bittelli et al., 2008).

The dissolved ‘atmosphere’

In their treatise *The atmosphere of the soil: Its composition and the causes of variation*, Russell and Appleyard (1915) stated “Thus it appears that there are two atmospheres in the soil: one present as free gas filling the pores, and practically as rich in oxygen as ordinary air, the other dissolved in the surface films of water and other substances, almost devoid of oxygen and consisting mainly of carbon dioxide with some nitrogen”. Using Russell and Appleyard (1915) terminology, we can refer to compounds including not only O₂, CO₂ and N₂, but other biogenic or soluble gases such as N₂O, NO, NH₃ and CH₄, as occupying two distinct soil ‘atmospheres.’ While the soil atmosphere comprised of gas-filled pores is of critical importance in regulating the transport of gases within the soil and in exchange with the above-ground atmosphere, the atmosphere comprised of gases dissolved in soil water is of critical importance because it is the medium for biological and chemical activity. Although our understanding of the dissolved atmosphere has been expanded considerably since 1915, the most conspicuous feature is the same as in the gas-phase, i.e., O₂ tends to be depleted and CO₂ increased in soil solution relative to water in equilibrium with the above-ground atmosphere. This effect may be further enhanced because the rate of diffusion in liquid is substantially less than in the gas phase, with diffusion coefficients generally differing by a factor of 10,000 (Table 1). Another important property affecting dissolved gas concentrations is the Henry’s

Table 1 Henry’s Law constants and diffusion coefficients for major atmospheric and trace gases in soils.

Gas	Henry’s Law constant at 25 °C (K_H^{25}) ^a $\frac{\text{mol}}{\text{L} \cdot \text{atm}}$	Henry’s Law temperature dependency constant (TDC) ^b K	Diffusion coefficient in water (D_{water}) ^c $\frac{\text{cm}^2}{\text{s}}$	Diffusion coefficient in air (D_{air}) ^c $\frac{\text{cm}^2}{\text{s}}$

^bTemperature dependence constant (TDC) to determine Henry’s Law constant at any temperature (T, K) using: $K_H^T = K_H^{25} \exp(TDC * (T^{-1} - 298.15^{-1}))$. From NIST Chemistry WebBook, SRD 69, <https://webbook.nist.gov/chemistry/>.

^cDiffusion coefficients in water (D_{water} , cm² s⁻¹) and air (D_{air} , cm² s⁻¹) determined using the U.S. EPA On-line Tools for Site Assessment Calculation, <https://www3.epa.gov/ceampub/learn2model/part-two/onsite/estdiffusion-ext.html>.

Law constant (K_H) which describes the extent to which a compound will partition between gas and liquid phases under equilibrium conditions. For example, the K_H values in Table 1 can be used to estimate the dissolved concentration (C_d , mol L⁻¹) based on the gas-phase partial pressure (P_g , atm) using

$$C_d = P_g K_H \quad (1)$$

The main gases present in soil fall into three categories with respect to their tendency to partition to the liquid phase, with N₂, O₂ and CH₄ having K_H values that are approximately 10 times less than N₂O, NO and CO₂, which are in turn approximately 1000 times less than HONO and NH₃ (Table 1).

Soil gas-phase dynamics

Respiration and oxygen uptake

Respiration carried out by plant roots and soil microbes are commonly referred to as autotrophic and heterotrophic respiration, respectively, though it should be noted that some soil microbes including nitrifying bacteria are considered autotrophic because they utilize inorganic compounds as their source of carbon for biosynthesis. Rates of O₂ consumption and CO₂ production are directly related to the rate of plant and microbial growth, which in turn is related to several environmental factors including air and soil temperature, substrate availability, and soil moisture (Ben-Noah and Friedman, 2018; Glinski and Stepniewski, 1985). Most notably, autotrophic and heterotrophic respiration both tend to increase with increasing temperature.

Under aerobic conditions and when carbohydrates are the predominant carbon source, the amounts of CO₂ produced and O₂ consumed on a molar basis sometimes tend to be about equal, and therefore the ratio between them (CO₂ consumed per O₂ produced), which is commonly referred to as the respiratory quotient (RQ), tends to be approximately 1.0. An estimate of the RQ can be used, for example, to estimate O₂ consumption when only CO₂ respiration data are available, which is often the case because the latter is usually more readily measured. However, deviation of RQ away from 1.0 will tend to occur when portions of the soil volume become anoxic, when carbon sources other than carbohydrates are being metabolized, or when evolved CO₂ becomes converted to soluble carbonates under alkaline conditions (Angert et al., 2015; Glinski and Stepniewski, 1985; Ben-Noah and Friedman, 2018). Under these conditions, estimating O₂ based on an assumed RQ value of 1.0 can lead to substantial errors.

Heterogeneity and variability

Because soils are multi-phasic and physically, chemically and biologically heterogeneous, the composition of soil air can differ depending on the spatial scale at which it is characterized. On the scale of the soil profile (cm to m), concentrations of O₂ in soil layers near the surface (soil-atmosphere interface) will be closer to ambient levels and generally tend to decrease with depth. However, substantial spatial variation may also occur laterally and at small (<1 mm) spatial scales due to the presence of high biological activity and rapid O₂ consumption occurring close to incorporated fertilizers or manure (Nguyen et al., 2017), naturally occurring organic materials undergoing decomposition (Parkin et al., 1987), or due to active root O₂ uptake. Soil-water content, texture and structure affect the ability of gases to move through soil pores and can further limit the rates of O₂ diffusion into such regions of high O₂ consumption. Further restriction to gas transport can be presented by the presence of mucilage layers around plant roots (Ben-Noah and Friedman, 2018). These factors can result in the interior of large soil aggregates becoming anoxic even though O₂ levels in the larger inter-aggregate pore spaces may be relatively high (Renault and Stengel, 1994; Ebrahimi and Or, 2015; Højberg et al., 1994). The spatial distributions described above for O₂ tend to be reversed for biogenic gases, i.e., gas concentrations tend to be smaller close to the soil-atmosphere interface and to increase with depth and within soil aggregates. Soil aggregate size will interact with hydration cycles and carbon availability to determine O₂ availability and therefore net production of biogenic gases such as N₂O and CH₄ inside of soil aggregates (Ebrahimi and Or, 2018).

In addition to small-scale spatial variations, substantial temporal variations in overall soil-gas composition and in the concentrations of individual gases can occur, for example as a result of diel and seasonal changes in radiation and temperature which affect microbial and/or plant activities. At a given location, soil O₂ uptake rates, responding to changes in autotrophic or heterotrophic respiration, tend to change (i) at hourly time scales over the course of the day in response to diel changes in temperature, (ii) over seasonal time scales in response to changes in temperature and shifts in vegetation activity, and (iii) may also vary from year to year due to inter-annual weather variation (Glinski and Stepniewski, 1985; Ben-Noah and Friedman, 2018). Soil concentrations of O₂ and CO₂ also depend upon the rate that the soil is able to exchange these gases with the atmosphere via diffusion and convection. The diurnal and annual variabilities in soil gas concentrations are generally much greater for clayey soils than for sandy soils due to the ability of sandy soils to transmit gases at a higher rate (larger soil-gas diffusion coefficients and air permeabilities) and maintain more constant concentrations.

Large variations in soil respiration have been measured across different ecosystems and climatic regions which are expected to affect the soil aeration status (Bond-Lamberty and Thomson, 2010; Jian et al., 2021). Assessing 245 plant species from across the globe, Han and Zhu (2021) found that species-specific root respiration showed 60-fold variation and was positively correlated with root N concentration and negatively correlated with root tissue density, with deciduous having significantly greater root respiration than evergreen species. In managed agricultural systems, activities such as tillage (Venterea et al., 2006) and fertilizer amendment (Nguyen et al., 2017) can substantially affect soil respiration rates and O₂ availability.

Because both heterotrophic and autotrophic respiration tend to increase with temperature, there is a concern that increasing temperatures associated with greenhouse gas-driven climate change will force increased soil respiration and concomitant losses of soil carbon to the atmosphere. However, soil respiration is considered to be the least well-constrained component of the terrestrial carbon cycle due to large uncertainties which complicate the modeling of soil respiration and its response to temperature and other factors across ecosystems and climatic regions (Jian et al., 2021). For example, studies have found that plant respiration responses to temperature were less pronounced when plants are allowed to acclimate to increasing temperatures (Bryla et al., 2001) and that root and rhizosphere respiration were more temperature-sensitive than microbial respiration alone, especially in colder regions (Li et al., 2020). Other related concerns include effects of altered snowfall in temperate regions (Aanderud et al., 2013) and soil warming in high-latitude regions (Elberling and Brandt, 2003) on release of CO₂ due to altered soil respiration and/or physically trapped CO₂.

Other gas production processes

The majority of gas production in soil results from oxidation-reduction (or redox) reactions (Glinski and Stepniewski, 1985; Hillel, 2004). These processes are generally connected with the transfer of electrons from soil organic matter (or organic contaminants) to oxidized inorganic compounds catalyzed by enzymes produced by soil microorganisms. Some soil microbes, such as nitrifying bacteria, are lithotrophs that obtain energy by transferring electrons among different inorganic compounds. For well-aerated conditions (aerobic), O₂ is the electron acceptor. When O₂ becomes limiting (anaerobic), other substances will accept electrons or be reduced. Examples of compounds that can be reduced under anaerobic conditions are nitrate (denitrification), manganic manganese, ferric iron, sulfate, and perchlorate (a natural and anthropogenic contaminant). In waterlogged or very wet soils and sediments that are unable to transmit O₂ sufficiently fast through the profile, O₂ is the first to disappear followed by nitrate and then sequentially by the reduction of manganese, iron, and sulfate. Perchlorate is reduced at about the same point as nitrate. Several toxic organic chemicals also undergo redox reactions that greatly affect the kind and toxicity of the reaction products.

Soil O₂ availability can be a critical variable with regard to the production of other gases in soil. As O₂ levels decrease and other compounds serve as electron acceptors, the types of gases generated from the predominant redox reactions also tend to change. This can result in important shifts in the composition of gases emitted to the atmosphere and the net greenhouse gas impacts of those emissions. These effects are particularly evident with respect to soil carbon and nitrogen cycling processes because they affect not only CO₂ but more potent greenhouse gases including methane (CH₄) and nitrous oxide (N₂O). As O₂ levels decrease, processes that consume CH₄ tend to decrease, while processes that produce CH₄ are promoted. The amounts of N₂O produced from both nitrification and denitrification also tend to increase as O₂ levels decrease (Venterea, 2007). Soil O₂ levels can also affect the production of gases that are not greenhouse gases but have other ecological impacts, including nitric oxide (NO) produced during nitrification or denitrification, and hydrogen sulfide produced when sulfate is reduced. Some gases produced in soils are not necessarily associated with redox reactions. When fertilizer materials such as urea and ammonium salts are applied to the soil, reactions can occur, particularly in soils with a pH greater than about 7.5 or 8, that produces ammonia gas (NH₃). Fairly large emission of NH₃ can occur, for instance, if urea is applied to the soil surface since urea hydrolysis results in a large increase in pH near the fertilizer granules, with NH₃ being emitted. The deeper the material is placed, the less NH₃ will be emitted. Ammonia gas may also be produced in soil from the incorporation of animal waste.

In addition to O₂, gases including hydrocarbons, N₂O, NO, CH₄, and some sulfur gases may move from the atmosphere into the soil and be consumed by biological processes. Thus, the soil may act as a significant sink for atmospheric gases under some circumstances.

Some biogenic gases, including CO₂, HONO and NH₃, participate in acid/base reactions that alter their molecular form in a manner that affects their phase stability. For both CO₂, which exists in equilibrium with water as carbonic acid (H₂CO₃), and for HONO, at higher pH, as the acidic species tend to become deprotonated, their ionic forms are increasingly soluble and therefore there is decreased partitioning of the protonated forms to the gas phase. In contrast, partitioning of NH₃ to the gas phase increases at increased pH due to decreased protonation of NH₄⁺ to favor more NH₃ in solution. In this case, the amount of NH₃ gas emitted depends not only on acid/base (NH₃/NH₄⁺) reactions, and therefore on pH, but also depends on soil surface reactions, i.e., sorption or cation exchange of NH₄⁺. Thus, for example, in soils with similar pH and similar total NH₃ + NH₄⁺ levels, soils having greater NH₄⁺ sorption capacity will have a smaller proportion of the dissolved N in the form of NH₃ (Venterea et al., 2015) and therefore less likelihood of emitting gaseous NH₃.

Gas exchange mechanisms

Diffusion

Diffusion is considered to be the principal mechanism driving the exchange of gases between the soil and atmosphere. The diffusion velocities of gas mixtures in soil are related to each other in a complex manner dependent upon the mole fraction of each gas, the molar fluxes of each gas, and the binary diffusion coefficient of each gas pair. General equations for steady transport of a multicomponent mixture of gases have been developed based on gas kinetic theory (Curtiss and Hirschfelder, 1949). If gravity effects are ignored or diffusion occurs only horizontally, the well-known Stefan-Maxwell equations provide the theoretical framework for diffusion of gases in soils. Fick's law is generally applicable for only a few special cases (Jaynes and Rogowski, 1983). One of these cases is for the diffusion of a trace gas in a binary mixture, meaning that the mole fraction of the trace gas is small. Since the binary diffusion coefficients of N₂-air and O₂-air are very similar and CO₂ may be considered to exist in trace

amounts, the diffusion of the two major gases associated with aeration may come under this case. Diffusion of some of the other gases existing in soil may not meet this criterion, however (Rolston and Moldrup, 2002).

Assuming that the special case conditions are met, Fick's law is given by:

$$\frac{M_g}{At} = f_{g,d} = -D_p \frac{dC_g}{dx} \quad (2)$$

where M_g is the amount of gas diffusing (kg gas), A is the cross-sectional area of the soil (m^2 soil), t is time (s), $f_{g,d}$ is the gas flux density ($kg \text{ gas } m^{-2} \text{ soil } s^{-1}$) due to molecular diffusion, C_g is concentration in the gaseous phase ($kg \text{ gas } m^{-3} \text{ soil air}$), x is distance (m soil), and D_p is the soil-gas diffusion coefficient ($m^3 \text{ soil air } m^{-1} \text{ soil } s^{-1}$).

The soil-gas diffusion coefficient is the main variable controlling the degree of soil aeration. It is largest when the soil is dry and approaches zero as the soil becomes very wet or saturated. The D_p has been related both empirically and theoretically to the soil-air content by a number of authors (Moldrup et al., 2013; Ben-Noah and Friedman, 2018). Since discrepancies between measured soil-gas diffusion coefficients stemming from Eq. (1) and those calculated from the many empirical equations occur, it is often desirable to measure the soil-gas diffusion coefficient for particular situations. Laboratory methods using soil cores and field methods for measuring soil-gas diffusion coefficients have been developed (Rolston and Moldrup, 2002).

Convection

In addition to molecular diffusion processes, soil gases may also exchange with the atmosphere through convection (advection). Convective flow of gases means that the whole air parcel is moving through soil pores due to a pressure difference (gradient) between the soil and the atmosphere. Pressure gradients may develop due to barometric pressure changes in the atmosphere; wind blowing across the soil surface or against a hill or other landscape feature; infiltration of rainfall or irrigation water into the soil, soil-water redistribution, and evaporation; temperature differences across the upper part of the soil profile; and density differences due to high concentrations of gases that have densities much different than air (Scott, 2000; Jury and Horton, 2004).

Convective gas flow is described by a form of Darcy's Law

$$f_{g,c} = -\frac{K_a}{\mu} \left[\frac{dP}{dx} \right] \quad (3)$$

where $f_{g,c}$ is the flux density of gas due to convection ($m^3 \text{ gas } m^{-2} \text{ soil } s^{-1}$), K_a is the air permeability ($m^3 \text{ gas } m^{-1} \text{ soil}$), μ is the viscosity of the gas mixture (Pa s), P is pressure (Pa), and x is distance (m soil).

Air permeability is strongly influenced by soil-water content. Air permeability attains a maximal value for dry soil and decreases as the soil becomes wet until it reaches zero at saturation. This is caused by progressive blockage of the soil pores by water. Several field and laboratory methods for measuring K_a have been developed involving either steady-state or non-steady-state flow, though steady-state measurements of gas permeability are preferred. Most field methods are based on the same principles as the laboratory methods, i.e., they involve measuring the flow rate of air through a soil column under known pressure differences across the column.

Convective processes occur rapidly and sporadically. Thus, it is very difficult to observe, measure, and predict the gas exchange that occurs by convection. During infiltration into soil, there is ample evidence that air pressure increases ahead of the water wetting front, and convection of gases occurs. It is often assumed that diffusion is the predominant gas exchange process because it is operating continuously whereas convection occurs episodically (Ben-Noah and Friedman, 2018). Of the convective processes, rainfall and irrigation may contribute the most to aeration of soils, with estimates that rainfall may account for 7–9% of total aeration. Adequately quantifying these processes and being able to predict and model convective flow processes is a goal yet to be fully attained.

Aeration requirements

Plants

The plant response to inadequate aeration or lack of O_2 is highly dependent upon the plant species, stage of growth, and upon several soil and environmental conditions such as temperature, water relations, and occurrence of toxic byproducts of anaerobic conditions. The response of plants to inadequate aeration may be due to either direct or indirect effects. The direct effect is because of the lack of oxygen for root respiration. The indirect effect is due to changes in redox conditions that affect nutrient and water availability, soil pH, buildup of toxic concentrations of metabolites and metals, and the viability of pests and diseases (Glinski and Stepniewski, 1985; Ben-Noah and Friedman, 2018).

The direct effect of lack of O_2 or slow diffusion of O_2 to plant roots has been characterized by a measurement called the Oxygen Diffusion Rate (ODR). The ODR is measured by placing a cylindrical platinum electrode into the soil (Stolzy and Letey, 1964). Oxygen is reduced at the electrode surface and creates a current that can be measured. Diffusion of O_2 to the water covered electrode is meant to mimic the diffusion through the water film around roots. Many studies have attempted to relate the ODR to plant response (Glinski and Stepniewski, 1985; Ben-Noah and Friedman, 2018). ODR values smaller than about $0.2 \mu g \text{ cm}^{-2} \text{ min}^{-1}$ indicate potentially poor aeration for many plant species. Values larger than about $0.4 \mu g \text{ cm}^{-2} \text{ min}^{-1}$ are indicative of relatively good aeration for growth of most plants.

The plant symptoms of poor aeration are poor root growth or root death, negative geotropism of roots, depressed shoot growth, wilting, leaf senescence, abortion of flowers, and termination of shoot apex growth (Glinski and Stepniewski, 1985). Poor aeration may also result in decreased transpiration; accumulation of ethylene, ethanol, and other metabolites; and decreased uptake of nutrients, most notably nitrogen, potassium, and phosphorus. Substantial variation in the sensitivity of nutrient deficiency, and other negative impacts, to O₂ availability has been observed among different plant species (Ben-Noah and Friedman, 2018; Glinski and Stepniewski, 1985). Reduced conditions in soil may also result in increased solubility of some chemicals that are toxic to plants.

Remediation of contaminated soils

With the large use of chemicals in modern society, both inorganic and organic chemicals, either intentionally or accidentally, end up in soil as contaminants with varying degrees of toxicity (Gerstl et al., 1989). Large amounts of petroleum products end up contaminating soil, both as point and non-point sources of pollution. The hydrocarbons in crude petroleum include alkanes, cycloalkanes, aromatics, polycyclic aromatics, asphaltenes, and resins. In addition, chlorinated solvents, pesticides, detergents, metals, and other kinds of chemicals may pollute soil. Microbial processes in soil can degrade many of the organic compounds, but the biodegradability of various compounds is greatly influenced by their physical state and toxicity as well as soil environmental conditions including soil-water content, soil pH, temperature, levels of inorganic nutrients, levels of electron acceptors, and aeration (Baker and Herson, 1994). Organic contaminants provide a source of carbon to microorganisms, or they provide electrons, which the organisms can use to obtain energy. Metal contaminants may undergo redox reactions affecting their solubility and toxicity which also is dependent upon the aeration status of the soil.

In most cases, biodegradation of organic contaminants depends on the activities of aerobic organisms. Thus, the presence of an adequate supply of O₂ in the soil is essential for biodegradation or bioremediation to occur. In general, it takes 2–3 kg of O₂ to degrade 1 kg of petroleum hydrocarbon. On the other hand, some compounds like the highly chlorinated chemicals are not easily degraded and may be broken down more effectively under anaerobic conditions. Some chemicals, perchlorate for instance, are only broken down under anaerobic conditions. Table 2 gives a list of some chemicals indicating whether they are degradable by aerobic or anaerobic processes.

Measurement of soil gas chemical composition

Researchers have been measuring the composition of soil air for more than 100 years, initially focusing on O₂ and CO₂ (Russell and Appleyard, 1915). Early methods combined the installation of metal soil probes to varying depths that allowed for extraction of soil air samples that were then analyzed using the Haldane apparatus. More recently, soil probes have been developed that allow gas sample collection from soil depth intervals of 0.05–0.50 m while minimizing physical disturbance and accounting for dilution effects (Petersen, 2014). Vertical profiles of gas concentrations over smaller depth intervals (e.g., 20 mm) can be obtained in undisturbed soil cores using horizontally inserted needles as probes (Venterea and Rolston, 2002). Samples collected via probes can be analyzed by gas chromatography or chemiluminescence to detect a wide range of soil gas species including O₂, CO₂, NO, N₂O and CH₄ or can be equipped with in situ sensors that can provide semi-continuous measurement of CO₂ and O₂ without the need for sample extraction (Chen et al., 2005; Owens et al., 2016; Jarecke et al., 2016). Planar optode technology allows for time lapse visualizations of soil O₂ concentration dynamics in two dimensions (Nguyen et al., 2017). Microelectrodes for in situ measurement of O₂ concentrations at scales of <50 mm have been in use for decades (Lemon and Erickson, 1952) and improvements in the technology are still underway including for measurement of other gases including N₂O (Xing et al., 2021; Revsbech, 2021). Due to the specialized methods and equipment required to directly quantify soil-gas O₂ concentrations, soil-water content or other indices such as WFPS or relative diffusivity (Owens et al., 2016) are often used to infer soil O₂ status, although such inference does not account for other factors such as O₂ consumption or transport through water-filled pores which may vary independent of water content.

Table 2 Organic chemicals and their biodegradability.

<i>Chemical class</i>	<i>Examples</i>	<i>Biodegradability</i>
Aromatic hydrocarbons	Benzene, toluene	Aerobic and anaerobic
Ketones and esters	Acetone, methyl ethyl ketone	Aerobic and anaerobic
Petroleum hydrocarbons	Fuel oil	Aerobic
Chlorinated solvents	Trichloroethylene, perchloroethylene	Aerobic (methanotrophs), Anaerobic (reductive dechlorination)
Polyaromatic hydrocarbons	Anthracene, beno[a]pyrene, creosote	Aerobic
Polychlorinated biphenyls	Arochlors	Unclear
Organic cyanides		Aerobic

Adapted from Baker KH and Herson DS (1994) *Bioremediation*. New York: McGraw-Hill.

Summary

Aeration is the interchange of various gases between the atmosphere and soil and the various reactions that either consume or produce gases in the soil. The composition of soil air depends on the relative magnitude of both the sources and sinks of the various gas components, the interchange between soil air and atmospheric air, and the partitioning of the gases between the gaseous, liquid, and solid (mineral and organic matter) phases of the soil. The two major gases associated with aeration are oxygen (O_2) and carbon dioxide (CO_2) where O_2 moves from the atmosphere to soil and is consumed by plant roots and microorganisms and CO_2 moves from the soil, where it is produced by plant and microbial respiration, to the atmosphere. In addition to root and microbial respiration, O_2 may also be consumed by reaction with metals and other compounds. Soil O_2 availability can be a critical variable with regard to the production of other gases in soil including the potent greenhouse gases methane and nitrous oxide and gases that have important ecological impacts like nitric oxide and ammonia. The two transport mechanisms that result in aeration of soils are molecular diffusion and convection. Although convection can result in significant transport under certain situations, such as infiltration of rainfall or irrigation water into soil, diffusion is considered to be the dominant mechanism of exchange over the long term. The plant symptoms of poor aeration are poor root growth or death, negative geotropism of roots, depressed shoot growth, wilting, leaf senescence, abortion of flowers, and termination of shoot apex growth. Aeration is also important for the soil's ability to degrade pollutants. In most cases, biodegradation of organic contaminants depends on the activities of aerobic organisms. Thus, the presence of an adequate supply of O_2 in the soil is essential for biodegradation or bioremediation to occur. On the other hand, some chemicals will only degrade under anaerobic conditions. Knowledge of a chemical's biodegradability and whether the chemical will degrade under aerobic or anaerobic conditions plays a major role in design of effective bioremediation schemes.

Abstract

Capillarity emerges from interactions between air-water interfaces and soil surface and pore spaces. The tendency of water to adhere and spread over wettable surfaces while minimizing air-water interfacial area gives rise to spontaneous capillary rise in soil pores and crevices and to water retention against forces of gravity. Capillarity affects soil aqueous phase configurations that determine hydraulic pathways for water flow in unsaturated soil towards plant roots and surface evaporation, and sustain gas and nutrient diffusion pathways for biological activity. Capillary effects vary with soil type (surface and pore space properties) and contribute to the soil matric potential (along with film adsorption).

Key points

- The historical context of the capillarity concepts is provided.
- The ingredients of capillarity and their liquid-solid interactions are reviewed.
- Equilibrium capillary rise in cylindrical and angular capillaries is quantified.
- Dynamic aspects of capillarity are presented.

Introduction

The coexistence of gaseous, liquid, and solid phases in soil pores gives rise to various interfacial phenomena that, for example, lead to spreading of liquid droplets on solid surfaces, liquid spontaneously rising in narrow soil pores, interfacial mechanical stresses that hold water-wet sand grains together, or the entrapment and retention of liquid in crevices. These processes are attributed to the phenomenon of capillarity that controls the amount and configuration of water retained in soil following wetting events. Capillarity also controls aqueous phase connectivity critical for diffusion of solutes and for biological activity in soils (e.g., bacterial cell dispersion and microbial accessibility to nutrients). The control over water flow and solute transport rates, aspects of biological activity and water availability for plants highlight the central role of capillarity in agriculture, ecology, environmental and climatic processes. Focusing on the soil aqueous phase, we will review the interfacial properties of water and interactions with the soil solids to develop a quantitative representation of capillarity in soil.

An account of some experiments shown before the Royal Society; with an enquiry into the cause of the ascent and suspension of water in capillary tubes. *Philosophical Transactions of the Royal Society of London*, **30** (355): 739–747.

A brief historical perspective on capillarity

One of the earliest accounts of capillarity in a quantitative and now familiar way has been reported by the English scientist Jurin, (1718). His paper starts with posing an apparent paradox of perpetual motion in a capillary siphon tube pulling water from a reservoir and dripping it back to the same reservoir (Fig. 1). In his own words Jurin writes “Some days ago, a method was proposed to me by an ingenious friend, for making a perpetual motion, which seemed so plausible, and indeed so easily demonstrable from an observation by the late Mr. Hawksbee, said to be grounded upon experiment that, thou I am far from having any opinion of attempts of this nature, yet, I confess, I could not see why it should not succeed. “But as searches after things impossible in themselves are frequently observed to produce other discoveries unexpected by the inventor”. Jurin, (1718) correctly attributed the spontaneous rise of water into capillaries to “the attraction of periphery, or section of the surface of the tube, to which the upper surface of the water is contiguous and coheres”. About 100 years later, in 1805, two renowned scientists Simon Laplace in France and Thomas Young in England published independent studies on the phenomenon of a pressure jump across curved liquid-gas interfaces that are presented below as the Young-Laplace equation. In his essay on the cohesion of fluids, Young (1805) not only described the relations between curved interfaces and the onset of pressure in the liquid phase, but he also laid the foundation for the concepts of contact angle and wettability that we will explore later. In 1907, Edgar Buckingham introduced the concept of capillary potential for quantifying the attractions between water and soil solids and pores. Buckingham (1907, p. 29) wrote: “Then we may define ψ as the work required per centigram to pull water away from the mass of soil. We shall call ψ the capillary potential of the soil”. This definition of capillary potential remains a keystone in the quantitative representation of driving forces for flow in partially saturated porous media.

The origins of capillarity in porous media

The phenomenon of capillarity in porous media results from two primary opposing forces: liquid adhesion to solid surfaces, which tends to spread the liquid; and cohesive surface tension forces of liquids, which act to reduce liquid-gas interfacial area per unit volume of liquid. The resulting liquid-gas interface configuration under equilibrium reflects a balance between these forces. The phenomenon of capillarity is thus dependent on solid and liquid interfacial properties such as surface tension, contact angle, and solid surface roughness, and importantly, on the geometry of pore spaces as discussed below.

Surface tension

At the interface between water and other fluids (e.g., air) or soil solids, water molecules are exposed to different forces than are molecules within the bulk liquid. For example, water molecules in the bulk liquid are subjected to uniform cohesive forces due to formation of flickering (short-lived) hydrogen bonds with neighboring molecules on all sides. Water molecules at the air-water interface experience a net attraction into the liquid because of lower density of water molecules on the air side of the interface, with more hydrogen bonds being formed at the liquid side (Fig. 2). On average, water molecules at the surface form only three hydrogen bonds compared with the four formed in bulk water (Henn, 2003). The result is a membrane-like water surface that tends to contract and reduce the amount of its excess surface energy. Evidence suggests that water molecules are oriented with hydrogen atoms pointing into the vapor phase (Henn, 2003).

The surface tension reflects the amount of interfacial energy per unit area, or the energy required to bring molecules from the bulk liquid to increase the surface. Although the air-water surface may appear quiescent, it is a region experiencing violent collisions and heavy traffic from molecules condensing from the vapor phase or breaking loose (evaporating) from the surface with an average

Fig. 2 The air-water interface where water molecules at the surface experience different forces than in bulk with net attraction inwards (this creates the analogy of tension). The excess free energy at the surface implies that a force (equal to the surface tension) is required to bring water molecules from the bulk to increase surface area.

residence time of a molecule at the surface of less than 0.1 ms (Adamson, 1990). Water molecules are also exchanged with the bulk water at high rates (defined by the temperature and self-diffusion).

Liquids vary in their surface tension σ (Table 1) based on intermolecular forces. Surface tension typically decreases (linearly) with increasing temperature. Increasing temperatures and thermal expansion reduce the density of the liquid and cohesive forces (e.g., fraction of intact hydrogen bonds) with the thermal changes affecting the vapor pressure above the surface and solubility.

Table 1 Liquid-vapor interfacial tensions for various liquids.

<i>Liquid</i>	<i>Temp.</i> [°C]	<i>Surface Tension</i> [mN m ⁻¹]
Water	20	72.94
	25	72.13
Methylene iodide	20	67.00
Glycerin	24	62.60
Ethylene glycol	25	47.30

Soluble substances can increase or decrease surface tension. If the affinity of the solute molecules or ions to water molecules is greater than the affinity of the water molecules to one another, then the solute tends to be drawn into the solution and to cause an increase in surface tension (e.g., electrolytic solutes). For example, a 1% NaCl concentration increases the surface tension of an aqueous solution by 0.17 mN m^{-1} at 20°C . If, on the other hand, the attraction between water molecules is greater than their attraction to the solute molecules, then the latter tend to be relegated towards the surface, reducing its tension. That is the effect of many organic solutes, particularly detergents.

Contact angle formed between liquid and solid surfaces

When a liquid drop is placed on a solid surface, the angle formed between the solid-liquid (SL) interface and the liquid-gas (LG) interface (Fig. 3) is referred to as the equilibrium (or static) contact angle (γ). Two equivalent approaches have been used to describe the equilibrium contact angle on smooth and chemically homogeneous planar surfaces: (1) a force balance approach, and (2) an interfacial free-energy minimization. The force balance formulation considers interfacial tensions (σ_{ij}) as forces per unit length; hence the force balance at the contact line of a drop resting on a solid surface under equilibrium requires the vector sum of the forces acting to spread the drop (outward) to be equal to opposing surface tension and cohesion forces. The free-energy minimization approach regards interfacial tension as energy per unit area, and calculates changes in surface free energy (ΔF) due to infinitesimal displacement (ΔA):

$$\Delta F = \Delta A(\sigma_{SL} - \sigma_{GS}) + \Delta A \cos \gamma \sigma_{LG} \quad (1)$$

The result is identical whether considering the minimization of free energy, with $\Delta F/\Delta A = 0$, or taking a balance of forces tangential to the solid surface; both cases yield the Young equation:

$$\sigma_{LG} \cos \gamma + \sigma_{SL} - \sigma_{GS} = 0 \quad (2)$$

with L , G , and S indicating liquid, gas, and solid, respectively, and σ_{ij} the respective interfacial surface tensions. The equilibrium contact angle is therefore:

$$\cos \gamma = \frac{\sigma_{GS} - \sigma_{SL}}{\sigma_{LG}} \quad (3)$$

Liquids that are attracted to solid surfaces (adhesion) more strongly than to other liquid molecules exhibit a small contact angle, and the solid is said to be 'wetable' by the liquid (Fig. 3A). Conversely, when the attractive forces within the liquid are larger than the adhesive force with the solid surface, the liquid 'repels' the solid and γ is large (Fig. 3B). Fig. 4 illustrates differences in wettability of a silt soil (Bachmann et al., 2000). In Fig. 4B a water droplet is resting on a soil surface that was treated to become water-repellent ($\gamma = 70^\circ$). In contrast, Fig. 4A depicts a wettable soil surface. In general, the contact angle of water on clean glass, and presumably on most soil minerals, is small, and for mathematical convenience is often taken as $\gamma = 0^\circ$. Note that for most natural soil surfaces $\gamma > 0^\circ$ (for clean quartz $\gamma \approx 20^\circ$).

Fig. 3 Liquid-solid-gas contact angles: (A) hydrophilic surface ($\gamma < 90^\circ$) where liquid wets the surface; (B) hydrophobic surface ($\gamma > 90^\circ$) where liquid 'repels' the surface.

Fig. 4 (A) Wettable silt soil surface ($\gamma \sim 0^\circ$); (B) treated water-repellent silt soil surface ($\gamma = 70^\circ$). Curved surfaces and capillarity

When the forces that spread the liquid (adhesion and spreading on solids, or gas pressure within a bubble) are in balance with surface tension that tends to minimize interfacial area, the resulting liquid-gas interface is curved. In porous media, the liquid-gas interface shape reflects the interplay of forming a specific contact angle with solids on the one hand, and energetic constraints that minimize interfacial area within a pore. As shown independently by Laplace (1806) and Young (1805), a pressure difference forms across the curved interface, where the pressure at the concave side of the interface is greater by an amount that is dependent on the radius of the interface curvature and the surface tension of the liquid. For a hemispherical liquid-gas interface having radius of curvature R , the pressure difference is given by the Young-Laplace equation:

$$\Delta P = \frac{2\sigma}{R} \quad (4)$$

where $\Delta P = P_L - P_G$ when the interface curves into the gas (e.g., water droplet in air); or $\Delta P = P_G - P_L$ when the interface curves into the liquid (e.g., air bubble in water, water in a small glass tube). In many instances a bubble may not be spherical, or an element of liquid may be confined by irregular solid surfaces, resulting in two different radii of curvature such as water held in pendular rings between two spherical solid particles (Fig. 5). The Young-Laplace equation for this case is given by:

$$\Delta P = \sigma \left(\frac{1}{R_1} + \frac{1}{R_2} \right) \quad (5)$$

Note that this equation reduces to Eq. (4) for spherical geometry with $R_1 = R_2$, and the sign of R is negative for convex interfaces ($R_2 < 0$) and positive for concave interfaces ($R_1 > 0$). For an interface forming in a linear crevice or within a fracture, $R_2 \rightarrow \infty$, hence Eq. (5) reduces to: $\Delta P = \sigma/R_1$, where R_1 equals half the fracture aperture.

Fig. 5 (A) Radii of curvature and shape of water held in pendular space between two spherical grains. Note that for two equal spheres with radius a , the relationship between R_2 and R_1 is given as: $R_2 = R_1^2 [2(a - R_1)]$. (B) Water menisci held between three spherical glass beads at different capillary pressures.

The capillary rise model

When a cylindrical glass tube of small diameter (capillary) is dipped into free water, a meniscus forms in the tube owing to the contact angle between water and the tube walls, and minimum surface energy requirements. The smaller the tube radius, the larger the degree of curvature and the pressure difference across the air-water interface (Fig. 6). The pressure at the water side (P_w) is lower than atmospheric pressure (P_0). This pressure difference causes water to rise into the capillary until the upward capillary force is balanced by the weight of the water column. In a cylindrical tube, the radius of meniscus curvature (R) is related to the tube radius r by $R = r / \cos \gamma$; consequently, the equilibrium height of capillary rise in a cylindrical tube with contact angle γ is:

$$h = \frac{2\sigma \cos \gamma}{\rho_w g r} \quad (6)$$

where g is the acceleration due to gravity, and ρ_w is the liquid density. For water at 20°C in a glass capillary with $\gamma = 0^\circ$, the capillary rise equation simplifies to: $h(\text{mm}) = 15/r(\text{mm})$. It is instructive to introduce here the concept of capillary length λ_C , given as:

$$\lambda_C = \sqrt{\frac{\sigma}{\rho_w g}} \approx 3 \text{ mm} \quad (7)$$

This length is used as a yardstick to gauge the relative importance of capillarity relative to gravity for different liquids. For example, the capillary length for water defines a limit for rain drop sizes (that seldom exceed this diameter, Villermaux and Bossa, 2009). For capillary rise applications, a factor of 2 is added to the term under the radical ($\lambda_C \approx 4.2 \text{ mm}$ for water). The ratio of pore size or capillary radius r to the capillary length λ_C squared defines a dimensionless number known as the Bond number (B_O) (Or, 2008):

$$B_O = \left(\frac{r}{\lambda_C} \right)^2 \quad (8)$$

For example, $B_O = 1$ marks the condition where capillarity and gravity forces are equal (for a combination of capillary size and liquid). For water in soil pores with radii larger than 4.2 mm ($B_O > 1$) gravity overcomes capillary forces and we may observe gravity dominated flow (preferential flow).

Capillarity in soils

The complex geometry of soil pore space creates numerous combinations of interfaces, capillaries, and wedges in which water is retained, and results in a variety of air-water and solid-water configurations. Water is drawn into or held by these interstices in proportion to the resulting capillary forces. Here again, we may define a macroscopic capillary length that gauges the importance of capillarity and gravity via the use of the soil sorptivity function. In addition, water is adsorbed on to solid surfaces with considerable force at close distances. Due to practical limitations of present measurement methods, no distinction is made between the various mechanisms affecting water in porous matrices (i.e., capillarity and surface adsorption). Common conceptual models for water retention in porous media and matric potential rely on a simplified picture of soil pore space as a 'bundle of cylindrical capillaries'.

Fig. 6 Capillary rise in cylindrical tubes with different radii.

Fig. 7 Idealization of natural soil pore spaces as equivalent cylindrical capillaries.

The primary conceptual steps made in such models are illustrated in Fig. 7. The representation of soil pores as equivalent cylindrical capillaries greatly simplifies modeling and parameterization of soil pore space and relies heavily on the capillary rise equation (Eq. 6).

Capillarity in angular pores

Cursory inspection of scanning electron micrographs of soils and other natural porous media (Fig. 8) shows that pore spaces formed by aggregation of primary particles and mineral surfaces tend to be angular and slit-shaped, rarely resembling cylindrical tubes. Such observations and other shortcomings of the 'cylindrical capillary' model have led to the development of new models for capillarity in angular and slit-shaped pores. Capillarity in angular pores is quite different from the behavior in cylindrical pores with equivalent cross-sectional area. For example, when angular pores are drained, a fraction of the wetting phase (water) remains in the pore corners (Fig. 9A). This aspect of 'dual occupancy' of wetting and nonwetting phases, not possible in cylindrical tubes, more realistically represents liquid configurations and the mechanisms for maintaining aqueous phase continuity in porous media. Liquid-filled corners and crevices play an important role in displacement and transport processes in partially saturated porous media. For all (regular and irregular) polygons with n corners, the total water filled area (Aw_t) at a given matric potential is simply the sum of the water-filled areas in each corner (Fig. 9A). This sum is given by the simple equation (Tuller et al., 1999):

$$Aw_t = r(\mu)^2 F(\alpha) \quad (9)$$

With

$$F(\alpha) = \sum_{n=1}^i \left(\frac{1}{\tan(\frac{\alpha_i}{2})} - \frac{\pi(180 - \alpha_i)}{360} \right) \quad (10)$$

where μ is the matric potential and $F(\alpha)$ is a shape factor dependent on pore angularity (corner angles α_i) only.

Fig. 8 (A) Thin section of Devonian sandstone, revealing angular pore space. (B) Scanning electron micrograph of calcium-saturated montmorillonite clay. Fig. 9 (A) Dual-occupancy of wetting and nonwetting phases in triangular pores; (B) liquid-vapor interfacial configuration in a triangular glass pore (~ 2 mm).

In contrast to a piston-like filling or emptying of circular capillaries, angular pores undergo different filling stages and spontaneous displacement in the transition from dry to wet soil conditions (or vice versa). As the soil dries, the remaining water is retained in crevices and pore corners by capillary forces. When the water potential increases, the radii of curvatures in the corners increase until they make contact and form an inscribed circle (in the pore cross section). Subsequently, liquid spontaneously fills up the pore in a process termed pore snap-on. When an angular pore is drained, air invades the central pore region first and gradually displaces liquid to the corners. For completeness, one must also consider the role of liquid films due to adsorption to solid surfaces.

Capillary rise in angular tubes

Capillary rise in angular tubes is a simple extension of the capillary rise in cylindrical tubes presented above (Eq. 6). Following [Bico and Querre \(2002\)](#), the capillary force (F) exerted over the tube's perimeter P is balanced by the liquid weight (W) in a tube of cross-sectional area A (under equilibrium conditions), and this force balance is expressed as:

$$F = P\sigma \cos \gamma = W = \rho_w g h A \quad (11)$$

where g is the acceleration due to gravity, ρ_w is the liquid density, γ is the liquid-solid-gas contact angle, and h is the height of capillary rise.

For a rigorous account of the total weight of the liquid in the examples depicted in [Fig. 10](#) (square cross section with sides a , or equilateral triangular tube with sides a), we must account for the weight of liquid fingers over the main meniscus at h . The total weight of the liquid for the square tube is calculated as:

$$W_{\text{square}} = \rho_w g h a^2 + 4\rho_w g \int_h^\infty \left(1 - \frac{\pi}{4}\right) r^2(z) dz \quad (12)$$

Fig. 10 Equilibrium capillary rise in angular tubes.

In equilibrium, the force balance (Eq. 11) yields the capillary rise height, h :

$$h_{\text{square}} = \frac{(2 + \sqrt{\pi}) \sigma \cos \gamma}{\rho_w g a} = \frac{3.77 \sigma \cos \gamma}{\rho_w g a} \quad (13)$$

For all practical purposes, however, the counterweight of liquid fingers over the main meniscus can be ignored (lowering the capillary height estimate by less than 6%) in favor of a much simpler approximation considering the first term on the RHS of Eq. (13) only. This simplification yields:

$$h_{\text{square}} \approx \frac{4 \sigma \cos \gamma}{\rho_w g a} \quad (14)$$

Similarly, for an equilateral triangular tube the capillary rise is approximately:

$$h_{\text{triangle}} \approx \frac{12 \sigma \cos \gamma}{\sqrt{3} \rho_w g a} \quad (15)$$

Dynamic aspects of capillarity

Capillary rise dynamics

The equilibrium height of fluid rise in a capillary (Eq. 6) does not contain any information regarding the rate of rise and the time scales for attaining equilibrium, which may be of significant importance for industrial and natural processes. Under certain conditions, we may apply a simple force balance between a driving capillary force F_σ :

$$F_\sigma = 2\pi R \sigma \cos \gamma \quad (16)$$

and a retarding viscous force F_η (assuming Poiseuille flow in a tube):

$$F_\eta = 8\pi\eta x \frac{dx}{dt} \quad (17)$$

to represent the rate of capillary flow into a horizontal cylindrical capillary. Additionally, we may introduce inertial forces according to:

$$m \frac{d^2 x}{dt^2} = F_\gamma - F_\mu \quad (18)$$

where m is the mass of the liquid in the capillary, x is distance, and t is time. Substitution of the forces (Eqs. 16 and 17) into Eq. (18) and integration (neglecting higher-order terms) yields the so-called Lucas-Washburn-Rideal (LWR) equation (Lucas, 1918; Washburn, 1921; Rideal, 1921):

$$x = \sqrt{\left(\frac{R \sigma \cos \gamma}{\eta} \right) t} \quad (19)$$

which describes the rate of liquid penetration into a horizontal capillary with the dependency of x on $\sqrt{t}$. It is interesting to note that Washburn's neglect of inertial effects and Rideal's truncation of higher-order terms (r^{-n} , $n > 2$) in his series solution yield the same solution (Eq. 19). Note that a similar dependency of x on $\sqrt{t}$ is observed for early stages of water imbibition into soil (during early infiltration where gravity is unimportant) and these relations are used to define soil sorptivity.

The analytical representation of dynamic capillary rise with gravity is mathematically challenging. Several simplified analytical solutions for the rate of capillary rise in vertical capillaries have been proposed, such as the following implicit solution:

$$\frac{\rho g R^2}{8\eta} t = z(t) - z_e \ln \left[1 - \frac{z(t)}{z_e} \right] \quad (20)$$

The solution diverges as $z(t)$ approaches the equilibrium capillary rise z_e (Eq. (6)). Another approximate solution has been proposed, based on the introduction of a retardation coefficient β :

$$z(t) = z_e \left(1 - \exp \left[-\frac{\sigma \cos \gamma}{\beta z_e} t \right] \right) \quad (21)$$

The solution converges to the equilibrium capillary rise z_e (Eq. 6) for long periods of time. Fig. 11A depicts comparison of Eqs. (20) and (21) with capillary-rise measurements of silicon oil (PDMS 10) in a glass capillary, with $r = 0.315 \text{ mm}$ ($\sigma = 20.1 \text{ mN m}^{-1}$; $\eta = 10 \text{ mPa}$; and $\rho = 0.935 \text{ kg m}^{-3}$) (Hamraoui and Nylander, 2002). The nondimensional retardation coefficient for water in glass capillaries ranges from $\beta = 0.5$ for large radii ($r > r_c$), representing friction dissipation due to contact line motion and contact angle adjustment, $\beta = 0.7$ for small radii ($r < r_c$) representing primarily viscous dissipation. The critical radius r_c is related to an interesting

Fig. 11 (A) Comparison of measurements and theoretical models for capillary rise dynamics of silicon oil (PDMS 10) in glass capillary with $r = 0.315 \text{ mm}$ (calculated curve from Eq. (21); classic Washburn equation from Eq. (20)); (B) inertia-induced oscillations during capillary rise of water in different glass capillary sizes (numerical simulations). Note that inertial oscillations vanish for capillaries smaller than $r = 0.474 \text{ mm}$ according to Eq. (22). Adapted from Hamraoui A and Nylander T (2002) Analytical approach for the Lucas–Washburn equation. *Journal of Colloid and Interface Science* **250**: 415–421.

feature of capillary rise in the presence of gravity, namely inertia-induced oscillations in large capillaries (Quere et al., 1999), as depicted in Fig. 11B. The inertial oscillations disappear in capillaries of radii smaller than r_c :

$$r_c = \frac{2(\sigma \cos \theta \eta^2 \rho^2 g^3)^{1/5}}{\rho g} \quad (22)$$

A comprehensive overview of the transition from inertial to viscous limited capillary rise is given by Fries and Dreyer (2008) and summarized in Fig. 12. Initially, capillary rise is primarily inertial (there is not enough liquid to be retarded by viscous/friction forces) and the capillary rise is proportional to t (elapsed time). Gradually, viscous forces become dominant, and the capillary rise regime expressed by the LWR solution emerges with capillary rise rate proportional to $\sqrt{t}$. Interestingly, the meniscus velocity during

Fig. 12 Dimensionless representation of dynamic capillary rise regimes transitions from inertial to viscous capillary rise rates (and ultimately to equilibrium height, h_{eq}). The driving force for all dynamic regimes is capillarity (surface tension and curved interfaces). The proportionality of the capillary rise rate $h(t)$ as a function of time for different regimes given by different solutions. Modified from Fries N and Dreyer M (2008) The transition from inertial to viscous flow in capillary rise. *Journal of Colloid and Interface Science*, **327**: 125–128.

the early inertial regime may vary from 0.38 m s^{-1} to 3.8 m s^{-1} as the capillary radius varies from $1000 \text{ }\mu\text{m}$ to $10 \text{ }\mu\text{m}$. These high interfacial velocities are particularly important during motion of infiltration and drainage fronts and these rapid velocities are associated with the Haines jumps (Haines, 1930) as shown by Moebius and Or (2014).

Dynamic contact angle

The contact angle formed between a flowing liquid front (advancing or receding) and a solid surface is not constant but reflects the interplay between capillary and viscous forces. The relative importance of these forces is often expressed by the so-called capillary number, $Ca = \eta v / \sigma$, with η the liquid dynamic viscosity, and v the contact line velocity. The dependency of the dynamic contact angle γ_D on the velocity of the contact line during complete wetting can be described by a nearly universal behavior according to the so-called Tanner law:

$$\gamma_D^3 = A Ca \quad (23)$$

where A is a constant (~ 94 for γ_D in radians). Eq. (23) fits the data of Hoffman for $Ca < 0.1$ and $\gamma_D < 130^\circ$ (Fig. 13). The complete range of Hoffman's data fitted to the empirical expression:

$$\gamma_D(\text{rad}) = \cos^{-1} \left\{ 1 - 2 \tanh \left[5.16 \left(\frac{Ca}{1 + 1.31 Ca^{0.99}} \right)^{0.706} \right] \right\} \quad (24)$$

as depicted by a continuous line in Fig. 13.

For conditions of partial wetting ($\gamma_s > 0$), the relationships between contact angle and Ca are less universal. It has been postulated that at low Ca the apparent dynamic contact angle remains close to the static angle but rapidly deviates when Ca exceeds the value for γ_s (Fig. 13). This postulate is formalized by the following expression:

$$\gamma_D^3 - \gamma_s^3 = A Ca \quad (25)$$

Additional examples of advancing and receding contact angle dependency on capillary number are shown in Fig. 14 (Hirasaki and Yang, 2002). Note that for receding contact angle there is a critical Ca above which the contact angle vanishes. The theoretical basis for the postulate in Eq. (25) was first derived by Voinov (1976), using hydrodynamic approximations near the moving contact line, resulting in:

$$\gamma_D^3 - \gamma_s^3 = 9Ca \ln(Y/Y_m) \quad (26)$$

where Y/Y_m is a ratio of macroscopic length over which the contact angle is defined ($\sim \text{mm}$) to molecular length where continuum theories fail ($\sim \text{nm}$). Application of Eq. (26) with $Y/Y_m = 10^5$ to the data of Hoffman is depicted in Fig. 13. A key shortcoming of such hydrodynamic models for a dynamic contact angle is the lack of consideration of the effects and interactions with solid surface properties. Most natural surfaces are seldom flat and dry, and propagation of contact lines invariably involves motion over precursory films that cover surface roughness and overcoming rough geometry during contact line motion.

Fig. 13 Experimental results of Hoffmann fitted with Eq. (24) (Hoffman, 1975), and approximations given by Eqs. (23) and (26). Note that, for water flow in soils, the capillary number Ca rarely exceeds the range of values between 10^{-6} and 10^{-4} (for $v = 1 \text{ mm s}^{-1}$, $Ca = 1 \times 10^{-5}$, Friedman, 1999). Note that for natural soil conditions, the contact angle for water is seldom close to 0° (as shown here), and the intercept for low Ca under most practical conditions will rarely fall below 20° .

Heterogeneous surfaces and microscale hysteresis

Contact angle on chemically heterogeneous and rough surfaces

Consider a chemically heterogeneous surface made up of patches of solids (or grains) with two different equilibrium contact angles γ_a and γ_b , and with the fraction of the area occupied by a solid given as f (Fig. 15). The apparent equilibrium contact angle (γ_e) for the composite surface is given by the semiempirical Cassie equation:

$$\cos \gamma_e = f \cos \gamma_a + (1 - f) \cos \gamma_b \quad (27)$$

An example of the Cassie law for contact angle of water on a sand surface with increasing amounts of hydrophobic grains is shown in Fig. 16. The Cassie law (Eq. 27) is in remarkable agreement with experimental data for sand (Fig. 16) and silt surfaces. An interesting extension of the Cassie law for porous surfaces (soil, fabric, etc.) predicts that the apparent contact angle (γ_e) should be proportional to surface porosity (n):

$$\cos \gamma_e = (1 - n) \cos \gamma_a - n \quad (28)$$

The negative sign associated with porosity is due to the nonwetting properties of empty pores (i.e., air with $\cos \gamma_{air} = -1$).

These concepts of mixed wettability can be incorporated into the capillary rise model (Eq. 6) where capillary rise takes place in slits formed between two walls of different wettability. The same study applies the Cassie law to liquid retention in porous media and demonstrates these effects on the hydraulic properties of unsaturated porous media with varying surface wettability. In addition to surface chemical heterogeneity, the roughness of a surface is known to alter its wettability properties by increasing the wettable surface area per unit projected area, and by enabling a complex interplay between macroscopic contact angle and microscale geometry, leading to gas entrapment and a patchwork of micro-interfaces underneath the wetting fluid. A spectacular demonstration of surface roughness-induced super hydrophobicity with a water drop resting on a fractal hydrophobic surface and forming a contact angle of about 170° is shown in Fig. 17A. Such enhanced hydrophobicity is not only important for a variety of engineering and industrial treatments aimed at waterproofing of surfaces and fabrics, but it may also be important for explaining wettability properties of natural soil surfaces. Assuming that surface roughness defined by the ratio of the real surface area relative to flat surface ($Ro = \Delta A / \Delta A_0$) affects only the solid-liquid and solid-vapor interfacial areas, minimization of surface free energy results in the so-called Wenzel equation:

Fig. 16 Application of the Cassie law to (A) experimental results of contact angle with sand surfaces containing different proportions of hydrophobic (treated) sand grains; and (B) an image of a water droplet on nonwetting sand forming a contact angle of 95° . Adapted from Bachmann J, Ellies A, and Hartge KH (2000) Development and application of a new sessile drop contact angle method to assess soil water repellency. *Journal of Hydrology*, **231–232**: 66–75.

Fig. 17 (A) Water drop ($r = 1\text{ mm}$) resting on fractal rough surface with $R_O = 4.4$ (Eq. 29); and (B) apparent contact angles as a function of surface microroughness for a range of surfaces with different wettability. Reproduced from Onda T, Shibuichi S, Satoh N, and Tsujii K (1996) Super-water-repellent fractal surfaces. *Langmuir*, **12**: 2125–2127.

$$\cos \gamma_e = R_O \cos \gamma \quad (29)$$

where γ is the static contact angle for a smooth surface of similar chemical composition (see scheme in Fig. 15B).

The scope of surface influence is more complicated than predicted by simple expressions such as the Cassie and Wenzel equations. Other factors such as details of roughness geometry, interfacial pinning, and air trapping conspire to accentuate surface wetting properties as shown in Fig. 17B. The scheme depicted in Fig. 17B is based on experimental results showing the apparent contact angle on a rough surface plotted against the static contact angle on a smooth surface with similar chemical composition (to isolate the influence of surface roughness). Subsequent studies have shown a range of behaviors and asymmetry between the hydrophobic ($\cos \gamma < 0$) and hydrophilic ($\cos \gamma > 0$) sides of Fig. 17B. It is interesting to note that certain roughness patterns induce formation of air patches trapped underneath the liquid (similar to water drops resting on surfaces of some plant leaves).

Capillarity and soil cohesion

An important consequence of the Young-Laplace equation (Eq. 5) is the onset of a tensile force that pulls soil particles together across pendular water held at grain contacts, which is a familiar phenomenon to anyone attempting to build a sandcastle on the beach. Keen (1924) and Haines (1925) developed basic equations that relate capillary-induced cohesion and particle size and water

Fig. 18 Sketch illustrating capillary cohesion between soil particles.

content of idealized soils (i.e., spherical grains of known radius). For equal-sized spherical grains, the tensile force F_{Cap} pulling the grains together is calculated as:

$$F_{Cap} = 2\pi R \sigma_{LV} \sin \phi \sin (\phi + \tau) - \Delta P \pi R^2 \sin^2 \phi \quad (30)$$

where R is the particle radius, ΔP is the Young-Laplace pressure (Eq. 5) with high negative values (tensile forces) for very small particles, ϕ and τ are the filling angles related to the amount of pendular water between grains (Fig. 18), and σ_{LV} is the surface tension of the liquid-vapor interface. These concepts have been embedded in calculations relevant to soil mechanics and provide a bridge between soil water retention and mechanical properties under certain simplifying assumptions. For example, [Ghezzehei and Or \(2000\)](#) have used these concepts to quantify rates of soil aggregate coalescence due to tensile (capillary) forces using a slightly modified version of Eq. (30) that considers flattening of contacts between aggregates.

Hysteresis

The amount of liquid retained in a porous medium is not uniquely defined by the value of the matric potential but is also dependent on the 'history' of wetting and drying. This phenomenon, known as hysteresis, is closely related to various aspects of pore geometry, capillarity, and surface wettability. The macroscopic manifestation of hysteresis in soil water retention (or soil water characteristic) is rooted in several microscale mechanisms, including: (1) differences in liquid-solid-gas contact angles for advancing and receding water menisci (Fig. 19A), which is accentuated during drainage and wetting at different rates; (2) the 'ink bottle' effect resulting from nonuniformity in shape and sizes of interconnected pores, as illustrated in Fig. 19B, whereby drainage of the irregular pores is governed by the smaller pore radius r , and imbibition is dependent on the larger radius R . Additional effects stem from pore angularity; (3) differences in air-entrapment mechanisms; and (4) swelling and shrinking of the soil under wetting and drying, respectively. From early observations to the present, the role of individual factors remains unclear, and hysteresis is a subject of ongoing research.

Fig. 19 Two microscale mechanisms for hysteresis in capillary behavior: (A) differences between advancing and receding contact angle; and (B) the 'ink bottle' effect depicting two different amounts of liquid retained in identical pores under the same matric potential. Note that we keep the capillaries horizontal to avoid gravity effects on imbibition and drainage processes.

Summary

Capillarity is central to the understanding of water behavior in shallow and partially saturated soils, it represents the roles of air-water interfaces and formation of contact lines that envelop water in soil. Capillarity reflects the forces that hold water in unsaturated soil against the action of gravity and give rise to spontaneous flow towards evaporating surfaces or plant roots. The configuration of remaining water in unsaturated soil is defined by capillarity and with it the hydraulic continuity required for mass flow. We reviewed the components of capillary rise in soil pores and dynamics of capillary processes. Capillarity imparts internal mechanical strength to partially saturated soil and granular media due to the action of tensile forces that pull grain contacts together.

Abstract

The famous Darcy model relates the pressure gradient and the hydraulic conductivity of a porous filter layer to the flow rate of water through the filter. This macroscale linear flow model for saturated water flow through porous media is central for a whole class of environmental and technical processes. We present the foundations, assumptions and limitations of the model.

Key points

- Linear flow model for water through porous media
- Flow rate depends on pressure gradient and bulk material conductivity
- Linear approximation only valid for laminar flow cases dominated by viscous forces

Definition and introduction

Darcy's law is a linear flow model for water flow through a saturated porous medium. In 1856 the French engineer Henry P.G. Darcy presented his famous equation (Darcy, 1856) stating that flow rate (q) depends on the pressure gradient (∇H) and on the hydraulic conductivity (K) (Eq. 1):

$$q = K \nabla H \quad (1)$$

Based on a series of experiments in Dijon, Darcy discovered that the flow rate through a saturated sand column was proportional to the hydraulic gradient (pressure difference) in the system. The coefficient of proportionality is termed the saturated hydraulic conductivity.

The flow and redistribution of water through soils is crucial for the hydrologic cycle and most terrestrial ecohydrological processes (Rodríguez-Iturbe, 2000). Although the flow of a liquid in a porous medium is a complex multi-phase process and soils have to be addressed as structured and dynamic systems (Rabot et al., 2018), the water flow at saturated and stationary conditions is a central reference for the function of different soils. Notwithstanding the limitations of his linear flow model, Darcy provided the first analytical solution to unsteady, saturated flow. Its relevance to a whole class of environmental and technical processes is undisputed.

The Darcy model

The first publication of the Darcy model is referred to as appendix D to his book about the public water infrastructure in the city of Dijon, France (Darcy, 1856). When addressing filtration through sand layers he conducted experiments to determine the laws of water flowing through the filters. Darcy demonstrated with sand column experiments (Darcy, 1856; see Fig. 3) that *the volume of*

Fig. 1 A water-saturated soil column to illustrate Darcy's law for saturated filter flow. Steady state when $Q_{in} = Q_{out}$.

water passing through a layer of sand of a given nature is proportional to the pressure and in inverse proportion to the thickness of the layers crossed. This led to his original equation for volume flux of filtered water at atmospheric pressure under the filter (Eq. 2):

$$Q = \frac{ks}{e}(H + e) \quad (2)$$

where Q is the volume of filtered water, k is a coefficient depending on the nature of the sand, s is the surface area of a filter, e is the thickness of the layer of sand, H is the pressure as height of the water on the filter (Fig. 1).

In later forms of the same equation, the nature of his equation as linear flow model becomes more clearly accessible as stated in Eq. (1): A flux (q [LT^{-1}]) through a porous medium is defined by the saturated hydraulic conductivity (K [LT^{-1}]) as the invert of the hydraulic resistivity of the porous medium and the pressure gradient (∇H [L^{-1}]) as pressure difference per filter length ($\nabla H = \Delta H/e$).

Linear flow models

The Darcy equation is one form of the general linear flow model defining a flux as conductivity times a gradient. Further examples for these models are given in Table 1. As such it is a macroscopic description of the flow process with fundamental significance – and with a series of assumptions and limitations.

In analogy to other linear flow models (Table 1) one can directly deduce the implications of the Darcy equation: Flow through a porous medium (i) requires an initial gradient to be depleted, (ii) is governed by a specific conductivity, and (iii) both terms are assumed to act linearly. The gradient is a difference of the driving potential (here water head e.g., as analog to the electrical potential in Ohm's law) acting on a cross section over a given depletion length (here, length of the filter). The specific conductivity is treated as material constant and can be understood as the inverse of the resistivity of the material against the gradient depletion (here hydraulic conductivity e.g. as analog to the electrical resistivity).

The strength of the Darcy equation resides in the general clarification that an observed flow through a filter layer is proportional to the gradient. Because hydraulic conductivity is used in topographic indexes like the soil-topographic wetness index (Walter et al., 2002) one should note that the actual flow can deviate substantially from the saturated hydraulic conductivity depending on this gradient. Likewise, measuring flow alone is insufficient to derive hydraulic conductivity as material property. The driving gradient has to be considered alongside.

In addition to the famous experiments with constant gradients, Darcy appears to have been the first to apply the linear flow equation for an unsteady flow through a filter with falling head at the upper side of the filter and constant atmospheric pressure at

Table 1 Overview about general linear flow models.

Equation	Quantity transported across a flow region	transport coefficient of flow region	difference in driving potential across system
Ohm's law of electric currents			
$I = \sigma \frac{\Delta V A}{L} = \frac{1}{R} V$	$I =$ electric charge per time (Cs^{-1}, A)	$\sigma =$ specific electrical conductivity (Scm^{-1}) or invert of resistance ($m\Omega^{-1}$)	$\Delta V =$ difference in electrical potential (V)
Darcy's law of fluid flow through a porous medium			
$Q = k \frac{\Delta h A}{L}$	$Q =$ volume per time [$L^3 T^{-1}$]	$k =$ hydraulic conductivity [LT^{-1}]	$\Delta h =$ difference in head of water column [L]
Fick's law of diffusion flux			
$J = D \frac{\Delta C A}{L}$	$J =$ mass per area per time [$ML^{-2} T^{-1}$]	$D =$ Diffusion coefficient [$L^2 T^{-1}$]	$\Delta C =$ difference in concentration [ML^{-3}]
Fourier's law of thermal conduction			
$q = K \frac{\Delta T A}{L}$	$q =$ heat flux density [MT^{-3}]	$K =$ Thermal conductivity [$MLT^{-3}\Omega^{-1}$] ($WK^{-1}m^{-1}$)	$\Delta T =$ difference in temperature [Ω]

Fig. 2 A water-saturated soil column to illustrate Darcy's law for saturated filter flow with falling head (h).

the lower outlet (Darcy, 1856, appendix D and E, Fig. 2). This was done by combining Eq. (1) with continuity of the flux (q) through a filter surface (s) resulting in changes of the head (dh) over time (dt):

$$\frac{q}{s} = \frac{k}{e}(h + e) = - \frac{dh}{dt} \quad (3)$$

Eq. (3) can be resolved to:

$$\ln(h + e) = \ln(h_0 + e) - \frac{k}{e}[t - t_0] \quad (4)$$

and thus

$$\ln q = \ln q_0 - \frac{k}{e}[t - t_0] \quad (5)$$

which allows for the determination of the filter properties based on falling head observations. The notation corresponds to the original and Eq. (2) with h as water head above the filter, e as filter length, t as time and q as drained volume. The subscript 0 refers to the initial variable values.

The Darcy experiment

The properties and background of the Darcy equation becomes clearer, when one revisits the original study (Darcy, 1856). The main focus resides on clearing water in different arrangements of sandy filter layers. Obviously, the recognition of the gradient-dependent filter flow is paramount for such a study as it allows the unravelling of the properties of the porous media and filter length from observed pressure differences and fluxes.

The central experiment was conducted with a sand column apparatus (Fig. 3 as reported in Brown, 2002). The sands from the banks of the Saône river were packed into long steel tubes with manometers at both ends and a tap at the bottom. Apparently, the water supply was directly connected to the laboratory's water system. Repeated experiments lead to the recognition of the linear relationship between gradient and flow scaled by the "material coefficient" (saturated hydraulic conductivity).

One should note the scale of the apparatus with a considerable filter length of about 3 m (the exact values differ between the figure and the manuscript description) and a tube diameter of 0.35 m.

Validity and limits of the model

In accordance to his experiments and application cases, Darcy himself was well aware about limits to his model. He noted that filter fluxes with moderate gradients through sandy layers should allow for the linear simplification. In the following, different dimensions and implications of inherent simplifications in Darcy's law will be explained. A summary of the validity limits is given in Fig. 4.

The conceptualization of the macroscale model is also referred to as "Darcy-scale." Actual microscopic processes including friction at the liquid-solid interfaces, non-linear scaling of the flow with the pore radius and dynamic viscosity are all subsumed into the macroscale constant for hydraulic conductivity (see Bernoulli's Principle (1738) and Hagen-Poiseuille equation (Hagen, 1839; Poiseuille, 1840). This reduction further implies cases to be limited to saturated conditions in essentially homogeneous and isotropic pore spaces.

Application of the Darcy equation to soil water and the extension to unsaturated cases

Classical soil physical measurement procedures strongly adhere to analyses in soil cores and packed physical models. As such, they remain within the general realm of soils as filter layers in the sense of Darcy. Obviously, Darcy's law required to be extended to allow for unsaturated (but stationary) conditions by defining hydraulic conductivity as a function of soil water content ($K(\theta)$) known as Darcy-Buckingham equation (Nimmo and Landa, 2005):

$$q = K(\theta) \nabla H \quad (6)$$

The conceptual idea behind this is that if the pore space is not fully occupied by water, water films along the solid particles of the soil exhibit longer pathways and thinner cross sections for the flow. One can therefore expect (i) K to decrease with decreasing water content and (ii) $K(\theta)$ to be a highly non-linear exponential function. Given that soil water content (θ) is not a complete state variable, its counterpart matric potential (the soil capillary tension sucking water into air-filled pore space, ψ) is also used to determine unsaturated hydraulic conductivity.

To overcome the limitation to stationary conditions, the water passage through different calculation nodes was described by the continuity equation of the mass balance:

$$\frac{\partial \theta}{\partial t} = - \frac{\partial q}{\partial z} \quad (7)$$

The change of soil water content ($\partial \theta$) in a calculation node over time (∂t) equals the change in drained volume ($-\partial q$) in space (∂z). Eq. (6) can be directly set into Eq. (7) yielding the well-known Darcy-Richards equation, which thus still adheres to the general linear foundation of Darcy's law.

Unsurprisingly, it has subsequently become a core topic of soil physics to define and resolve the limits of the well-known mismatch of heterogeneous pore space reality and multi-phase flow in soils with the assumption of macroscopic homogeneity, isotropy and linearity and laminarity. Practitioners should note that even modern analytical tools to measure saturated hydraulic conductivity and soil water retention characteristics in undisturbed soil cores still rely on the conceptual foundation of Darcy's law including the referring Darcy-scale. Although experimental evidence for the limitations of the Darcy equation has existed at least since Schneebeli (1955), technical capacities to resolve soil water dynamics at the actual pore level emerged only recently (Lucas et al., 2020).

Isotropy and scale (in)variance

Although Darcy referred to different layers of filter sands, a strong contrast of hydraulic properties, for example, between soil layers or under contrasting antecedent conditions, is omitted or subsumed in the model for an overall filter property. In contrast to the original experiments, with packed columns several meters in length, or sandy river banks, in most natural soils such isotropic conditions are rather rarely found (Gerke, 2006).

Among others, Miller and Miller (1956) derived Darcy's law from the Stokes equation by averaging sub-scale variance and boundary effects to the macroscopic Darcy-scale. To do so, they introduced four assumptions for their approximation:

1. The geometric properties of the solid part of the porous medium is homogeneous, isotropic and permanent so that these properties are independent of position, orientation and time.
2. The liquid is uniform in its surface tension, contact angle, density and viscosity throughout the flow system.
3. The properties of the gaseous phase are constant over the flow system.
4. All liquid and all gaseous proportions are connected so that neither isolated droplets nor bubbles exist.

Sposito et al. (1979) and others have presented further theoretical elaborations deriving the macroscopic description from fluid mechanics, Markov processes and statistical thermodynamics. Their studies highlighted many of the implications when reducing the complex multi-phase flow in soils to the linear flow model. They came to similar conclusions as Darcy himself, that *the theory would be expected to work best with coarse materials in the range of sands, and perhaps silts, at moderate liquid contents.*

Darcy-scale and representative elementary volume

Following the notion that models are generally valid at a specific scale, the definition of the representative elementary volume (REV) is deeply connected to the Darcy-scale, too. Given the four central assumptions by Miller and Miller (1956) and acknowledging the state of science in laboratory and field soil physical analytical procedures, the REV can hardly be unraveled from the Darcy-scale, when most measurements closely relate to the linear flow model.

Roth (2008) revisits the question of why scaling of water flow through porous media is so complicated. Darcy's law subsumes the many non-linear effects of the fluid (i.e., temperature, pressure and solute depending viscosity), of the pore space geometry (e.g., non-monotonous, non-circular capillaries) and of the multi-phase surfaces into one parameter in a linear model. The upscaling of

these microscale effects to the macroscale description is limited to cases and the extent to which the pore-geometry itself can be upscaled. The corresponding characteristic length of the REV must be large enough to fulfill the stationarity assumption (Roth, 2008), yet small enough to resolve driving processes (Vogel and Ippisch, 2008). To fulfill both requirements has been described as closure problem (Whitaker, 1986).

Transition to non-Darcian flow and non-uniform flow in soils

Despite uniform pore space characteristics, the observed flow has been found to deviate from the linear relation in the Darcy equation (Fancher and Lewis, 1933; Hansbo, 2001). Irmay (1958) interprets the Darcy equation as the first term in the more general and non-linear Forchheimer equation. At higher Reynolds numbers (as the ratio of inertial forces to viscous forces used to discern laminar and turbulent flow conditions), the non-linear contribution of inertia to the transport of momentum in the flow field become prevalent (Yazdchi et al., 2010, 2011) (see upper validity limit in Fig. 4). This transition is found to happen already for Reynolds numbers between 0.4 and 3 (Tachibana et al., 2017). Above the transition range a sharp decrease of the permeability coefficient was found in the same study, manifesting the shift toward turbulent fluxes at high Reynolds numbers.

The disagreement of observed soil water dynamics with the assumptions in Darcy's law have been debated also with respect to macropores (Beven and Germann, 1982, 2013) and fractures (Berkowitz, 1989). Measurements of non-uniform infiltration (Flury et al., 1994; Nimmo, 2021) question the applicability of Darcy's findings to natural and rarely saturated soils. The heterogeneous pore networks are particularly difficult to upscale to a unique macroscopic description. Moreover, dispute about the assumption of stationarity of the flow field as laminar flow is inevitable as the heterogeneity also hinders the inherently assumed perfect mixing (Jackisch and Zehe, 2018; Berkowitz and Zehe, 2020). For infiltration, Germann (2020) challenges the applicability of the Darcy-concept of filter flow even further by explaining water dynamics based on Newton's viscous shear flow.

After Hagen-Poiseuille (1841) the radius of a pore quadratically scales the mean velocity and enters the viscosity-based form to the power of 4. With non-uniformly distributed pore sizes, consequently the critical Reynolds number for laminar, creeping flow can be locally surpassed in pores with larger radius. Whitaker (1986) pointed to spatial deviations of the pressure and velocity within an assumed REV. In soils the non-uniform boundary conditions and variances in the flow field can become self-reinforcing when the pore structures become reconfigured (Zehe et al., 2021).

At the other end of the pore size spectrum, flow in clay soils with a very low hydraulic conductivity was also found to deviate from Darcy's simplification with pressure gradients building up before flow starts (Miller and Low, 1963) (see lower validity limit in Fig. 4). Unlike with Darcian flow with a continuous hydraulic head in the filter, pore pressure diffusion around adsorbed water at the large specific surface of the mineral-water interface was found to retard the flow reaction (Tang et al., 2016).

Summary

Darcy's linear flow model is fundamental for many environmental and technical processes as it clarifies that a pressure gradient needs to act on a porous media with a specific bulk resistance or conductivity to generate flow, depleting this gradient. As with most linear model approximations, special care has to be taken about the embedded assumptions and the limits for any application.

Abstract

Diffusion is the movement of a chemical substance in the gas or liquid phase along a chemical gradient and constitutes a primary mechanism of mass transfer in natural and engineered soil ecosystems. Many ecosystems services and functions in soils are linked to diffusion-controlled mass transfer processes in soil-aqueous and soil-gaseous phases. The mathematical framework describing diffusion in soil is based on Fick's laws of diffusion, with extended versions available for applications in multi-component mixtures. Diffusion coefficients in soil-aqueous and soil-gaseous phases are determined from measurements of chemical concentration over time using specific apparatus under controlled boundary conditions. Predictive-descriptive diffusivity models offer a fast and convenient alternative to estimate diffusion coefficients in both aqueous and gaseous phases using easily measurable soil properties.

Key points

- Diffusion-controlled processes constitute a primary mechanism of mass transfer in soil.
- The basic mathematical framework describing diffusion in soil is founded on Fick's laws.
- Half-cell and one-chamber methods are generally adapted to measure solute and gas diffusion coefficients, respectively.
- Predictive-descriptive models are used to estimate diffusion coefficients in soil from basic soil properties

Introduction

Diffusion constitutes a key mechanism by which mass transfer takes place in soils and other porous domains. The word 'diffusion' comes from the Latin *diffundere*, meaning *spreading out*. Technically, diffusion can be described as the net movement of chemical substances in a gas or a liquid in response to a chemical gradient, until a state of equilibrium prevails within the system with respect to the chemical species. Diffusion can also occur in solid state, but it is of little interest for applications in soil in comparison to important implications in liquid and gaseous states.

Diffusion is often referred to as a process that occurs along a concentration gradient, although the true energy gradient for movement is provided by the partial pressure (in the gas phase) or differential chemical potential (in the liquid phase) of the particular gas or chemical in the medium. A simple example is an airtight chamber that is partitioned into two compartments by a moveable middle plate in such a way that each unit is filled with two different gases, but at the same total pressure. Since the partial pressures of the two gases in the two units are different, removing the middle plate instantly makes a partial pressure gradient, causing the movement of two gases from high partial pressure to low partial pressure until the partial pressure gradients, and hence the net movement across any section, cease. A similar process occurs in a liquid solution for chemicals (or solutes) along a chemical potential gradient. Essentially, diffusion is non-directional and may occur in any direction where the particular gradient exists.

How does diffusion occur?

Diffusion originates from *Brownian motion*, the random thermal movement of ions or molecules at the microscopic scale, named after Robert Brown (1773–1858), the first to study the phenomenon (Brown, 1828). Given a chemical potential gradient, the probability is that molecules will make a net movement from high potential regimes to low potential regimes, the phenomenon referred to as diffusion. Diffusion can thus be interpreted as the macroscopic manifestation of Brownian motion occurring at the microscopic level. Because gradients in partial pressure or concentration are gradually lessened by diffusion but never eliminated, partial pressures (of gases) and concentrations (of solutes) become uniform only at an infinite time (although in practice many diffusive flows become too small to measure after a relatively short time).

In the absence of an advective flow, which occurs due to an induced pressure gradient, diffusion becomes the prominent mechanism of mass transport in soils (Bear, 1972). In the presence of advective flows, however, the magnitude of advective transport dictates the relative importance of the diffusive transport. Moreover, advective flow triggers *dispersion*, the enhanced mixing observed at microscopic scale due to the velocity fluctuation around soil particles: this should not be confused with diffusion. Though the two mechanisms are implicitly analogous, two distinct differences exist between diffusion and dispersion: dispersion is velocity-dependent whereas diffusion is not, and dispersion is controlled by the direction of flow but diffusion is essentially concentration-dependent irrespective of the flow direction (Fig. 1).

Fick's laws of diffusion

Adolf Eugen Fick (1829–1901) developed the pioneering mathematical framework to describe the phenomena of diffusion. The work has almost exclusively been used as the constitutive law to predict diffusive fluxes in continuum mechanistic models

Fig. 1 Schematic of the half-cell apparatus for measuring soil diffusion coefficient, D_s (top), initial and boundary conditions (middle) and a typical solute concentration profile across the cell length (bottom). Unpublished data from Hamamoto et al. (2009) on Nishi-Tokyo Andisol (bulk density = 0.7 g cm^{-3} ; saturation = 0.95).

(Fick, 1855). Fick's mathematical expressions are principally analogous to other classical flux equations in which flux is expressed proportional to a gradient in a property of interest in the system, with a system-specific coefficient as the proportionality constant. Fick's diffusion expressions came under two fundamental laws. Fick's first law of diffusion relates the diffusive flux to the concentration gradient as follows:

$$J = -D \frac{\partial c}{\partial x} \quad (1)$$

where J is the diffusive flux ($\text{mol m}^{-2} \text{s}^{-1}$), D is the diffusion coefficient ($\text{m}^2 \text{s}^{-1}$), c is the concentration (mol m^{-3}), and x (m) is the spatial dimension. The negative sign indicates that the diffusive fluxes are directed against the concentration gradient.

Combining Fick's first law of diffusion with the continuity equation (Eq. 2)

$$\frac{\partial c}{\partial t} = -\frac{\partial J}{\partial x} \quad (2)$$

invokes Fick's second law of diffusion (Eq. 3), which describes the one-dimensional spatial-temporal relation of diffusion as follows:

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial x^2} \quad (3)$$

where t is time (s). Though Fick's laws dominate in classical diffusion-controlled mass transfer applications due to their simplicity and reduced computational expense, the laws are applicable only for restricted cases as described below.

Maxwell-Stefan diffusion equation

Since the classical Fick's laws implicitly assume the presence of no other components affecting the flux of a specific chemical component, they are ideally applied for chemicals constituting a binary system with molecules in diluted concentrations. In a multicomponent system with individual components having comparable molar fractions, Fick's laws tend to yield inaccurate estimations. Therefore, the Maxwell-Stefan (MS) diffusion equation, an extended version of the Fick's equations, is generally applied to estimate diffusive fluxes in multicomponent mixtures. The MS constructive theory, developed independently by James Maxwell (for dilute gases) and Joseph Stefan (for liquids), can be presented as (Bird et al., 2007):

$$\nabla x_a = -\sum_{b=1}^N \frac{x_b N_a - x_a N_b}{D_{ab}} \quad (4)$$

where ∇ is vector differential operator (m^{-1}), x_a and x_b are the molar fractions of species a and b (dimensionless), respectively ($1 < a, b < N$; $a \neq b$), N_a and N_b are molar fluxes of species a and b ($\text{mol m}^{-2} \text{s}^{-1}$), respectively, D_{ab} is the binary diffusion coefficient ($\text{m}^2 \text{s}^{-1}$) for the gas pair a and b in a multicomponent system. Accordingly, for an N -component system, $N(N-1)/2$ number of binary diffusion coefficients are required (Bird et al., 2007).

Importance of diffusion in soil

Diffusion of chemical species in soil occurs in both aqueous and gaseous phases and hence plays a key role in natural and engineered soil ecosystems. Many useful regulatory and provisioning ecosystem services, ranging from nutrient cycling to pollutant transport, can be potentially linked to diffusion-controlled mass transfer processes.

In the vadose zone, diffusion becomes the dominant transport mechanism in water for dissolved chemicals when sufficient time has elapsed following infiltration and redistribution of water. Diffusion ensures an adequate supply of nutrients and dissolved ions to the depleted root zones caused by root uptake of essential plant nutrients. Dissolved oxygen, consumed during rhizosphere respiration and microbial metabolism, is continually replenished by diffusion of oxygen from distant soil-water systems. Deeper in the soil and at larger scale, diffusion offers a primary mode of communication between a stagnated aquifer and a coexisting flow domain, leading to the exchange and spreading of chemicals and contaminants. Diffusion predominates in engineered soil systems, which are hydraulically isolated, causing them to contain chemicals or waste materials. The efficiency of clean-up technologies for contaminated sites with dissolved contaminants largely depends on how well diffusive contaminant migration in the soil is understood.

Soil-gas diffusion, on the other hand, occurs predominantly in the gaseous phase, as gas diffusion in liquid is nearly a four-order-of-magnitude slower process than that in the air (Cussler, 2009). Soil-gas diffusion facilitates soil aeration by the continuous supply of oxygen to plant roots and prompt removal of root-zone carbon dioxide, thereby maintaining a healthy soil atmosphere for plant growth. Mitigation of diffusion-dominated emission of greenhouse gases from agroecosystems is essential to regulate future climate change. Volatile organic compounds may diffuse in soil from a leaky underground storage facility toward the ground surface and enter into overlying infrastructure through foundation cracks, thereby affecting indoor air quality (Unnithan et al., 2021). Landfills constitute another complex and unorthodox ecosystem, where diffusion and off-site emission of landfill gases (predominantly methane and carbon dioxide) may potentially lead to deadly catastrophes such as explosions or fire hazards.

Different diffusion regimes in soil

In porous media with a wide spectrum of differently-sized pores, diffusion becomes fundamentally pore size-dependent; the ratio of pore size to the size of the diffusing molecules dictates the governing diffusion mechanism. If pores have sizes smaller than the size of diffusing molecules, they are inaccessible and hence lead to a complete *impasse* (with no diffusion). When molecules are of comparable dimensions with pore size, other diffusion mechanisms may occur, initiated with *configurational diffusion* (Siddiqui et al., 2021). *Knudsen diffusion* is associated with pore sizes that are larger than that of molecules but are smaller than the mean-free distance of the molecules (Clifford and Hillel, 1986). In pore domains where pores are larger than the mean-free distance of molecules, *Fickian diffusion* predominates (Jaynes and Rogowski, 1983), and is very apparent in natural soils. A combination of different diffusion regimes is most likely to occur in soils with broadly ranging pore sizes, whereas the predominant pore domain size dictates the governing diffusion regime for specific molecular constituents. While different constitutive theories explain the aforementioned diffusion regimes, the Fickian-based mathematical framework is widely adopted to describe diffusion in applied soil science.

Diffusion coefficients in soil-liquid and soil-gaseous phases

Solute diffusion coefficient in soil

Diffusion of dissolved chemical constituents (referred hereafter as solutes) in the soil-liquid phase is typically characterized by the solute diffusion coefficient in soil, (D_s , $\text{m}^2 \text{s}^{-1}$), which can be conveniently derived from Fick's laws. Since different Fickian-based formulations appear in the literature to calculate solute diffusion coefficients, care must be exercised when comparing the coefficients calculated from different theoretical derivations.

Amongst different methods for the practical measurement of solute diffusion coefficients, the so-called half-cell method is the most popular. In brief, this comprises two halves of a cell, with one given a shot of the solutes, with the other being free of them. They are then brought into an instant and complete hydraulic contact, enabling the solutes to migrate from the treated cell to the untreated one, solely by diffusion.

The solute diffusion coefficient can be determined from the observed concentration vs. time data along the length of the half-cell, solving the diffusion equation under specified boundary conditions (Flury and Gimmi, 2002).

Governing equation

$$\frac{\partial c}{\partial t} = \frac{D_s}{R\theta} \frac{\partial^2 C}{\partial x^2} \quad (5)$$

where R is the retardation factor (dimensionless), and θ is the soil moisture content ($\text{m}^3 \text{m}^{-3}$).

Initial and Boundary conditions

$$\begin{aligned} \frac{\partial C(x=0, t > 0)}{\partial x} &= 0; \\ C\left(0 \leq x \leq \frac{L}{2}, t=0\right) &= C_0; \quad C\left(\frac{L}{2} < x \leq L, t=0\right) = C_i \\ \frac{\partial C(x=L, t > 0)}{\partial x} &= 0 \end{aligned}$$

Analytical solution

$$\frac{C - C_i}{C_0 - C_i} = 0.5 + \frac{2}{\pi} \sum_{m=1}^{\infty} \frac{\exp(-D_s m^2 \pi^2 t / RL^2 \theta)}{m} \cos\left(\frac{m\pi x}{L}\right) \sin\left(\frac{m\pi}{2}\right) \quad (6)$$

where C_0 is the initial liquid-phase concentration of the treated half-cell (g cm^{-3}), C_i is the initial liquid-phase concentration in the untreated half-cell (g cm^{-3}), L is the total column length (cm), and t is time (s).

Modeling solute diffusion

Measurement of the solute diffusion coefficient in soil is experimentally time-consuming and instrumentally challenging. Many practical constraints surround the half-cell method, including the difficulty in maintaining a continuously replenished reservoir of solutes in the treated cell, and the challenge to maintain a perfect hydraulic contact between the two half cells, particularly in low-saturation conditions (Flury and Gimmi, 2002). Therefore, it is a convenient practice to estimate D_s from easily-measurable properties such as soil moisture content (θ , $\text{m}^3 \text{m}^{-3}$) and total porosity (Φ , $\text{m}^3 \text{m}^{-3}$). Several predictive models are available in the literature including the classical Millington and Quirk (1961) model:

$$\frac{D_s}{D_{o,l}} = \frac{\theta^{10}}{\Phi^2} \quad (7)$$

where $D_{o,l}$ ($\text{m}^2 \text{s}^{-1}$) is the solute diffusion coefficient in free water. Olesen et al. (1996) found that the soil type-independent Millington and Quirk (1961) model often overpredicts the solute diffusion in soil and proposed the following empirical formulation:

$$\frac{D_s}{D_{o,l}} = 0.45\theta \left(\frac{\theta}{\Phi} \right)^{0.3b} \quad (8)$$

where b (dimensionless) is the Campbell pore size distribution parameter which makes the model (Eq. 8) soil type-dependent. Later studies, for example Olesen et al. (2000) and Moldrup et al. (2007), emphasized the presence of a 'percolation threshold' (θ_{th} , $\text{m}^3 \text{m}^{-3}$), a moisture content below which the diffusion ceases due to the presence of disconnected moisture regimes. A more generalized model incorporated with percolation threshold can be written as

$$\frac{D_s}{D_{o,l}} = H\theta(\theta - \theta_{th}) \quad \theta > \theta_{th} \quad (9a)$$

$$\frac{D_s}{D_{o,l}} = 0 \quad \theta \leq \theta_{th} \quad (9b)$$

where H is an empirically determined parameter by fitting the model to the measured data. Olesen et al. (2000) proposed a constant H ($=1.1$) regardless of soil type, whereas Moldrup et al. (2007) correlated H to soil type via clay content of the soil. Along the same line, later studies accounted for additional soil complexities in the model, for example Hamamoto et al. (2009) who empirically linked soil density (ρ_b) in functions for H ($=3.7\text{--}4.0\rho_b$) as well as θ_{th} ($=0.42\text{--}0.27\rho_b$).

A study from Hunt et al. (2014) discussed a theoretical framework for percolation threshold by combining the percolation theory and effective medium approach. The theoretical model includes a critical moisture content (θ_c , $\text{m}^3 \text{m}^{-3}$) which is conceptually analogous to the percolation threshold, and a moisture content at 'crossover point', (θ_x , $\text{m}^3 \text{m}^{-3}$), where transition from percolation to effective medium scaling takes place. The model takes the form of:

$$\frac{D_s}{D_{o,l}} = \frac{1 - \theta}{\theta_x - \theta_c} \left(\frac{\theta - \theta_c}{1 - \theta_c} \right)^2 \quad \theta_c < \theta < \theta_x \quad (10a)$$

$$\frac{D_s}{D_{o,l}} = \frac{\theta - \theta_c}{1 - \theta_c} \quad \theta_x < \theta < 1 \quad (10b)$$

Hunt et al. (2014) emphasized the exponent 2 (in Eq. 10a) as a universal scaling factor in the light of theoretical exposition of conduction properties, while a priori information is required to estimate the critical moisture contents.

Soil-gas diffusion coefficient

Founded on Fick's laws, the soil-gas diffusion coefficient (D_p , $\text{m}^2 \text{s}^{-1}$) characterizes the diffusion of gas in the functional soil gaseous phase. As observed with the solute diffusion, it is generally normalized with the gas diffusion coefficient in free air ($D_{o,g}$, $\text{m}^2 \text{s}^{-1}$) and expressed as soil-gas diffusivity ($D_p/D_{o,g}$), a parameter that can be related only to the porous media characteristics, mainly the air content (ϵ , $\text{m}^3 \text{m}^{-3}$) and tortuosity of the gaseous phase (τ , dimensionless). The tortuosity can be geometrically defined as the ratio between the true length a gas molecule will traverse between two points in space in a given time to the shortest (Euclidean) distance between the two points.

Chamber-based methods are generally used to measure the soil-gas diffusion coefficient with one-chamber or two-chamber approaches. A brief account of the one-chamber approach is mentioned here while descriptive information on both methods can be found elsewhere (Rolston and Moldrup, 2002).

The one-chamber apparatus typically consists of an air-tight chamber, provisioned at one end to mount the soil sample, and a mechanism to isolate the sample from the chamber often by means of a movable plate (Fig. 2). N_2 and O_2 are used as the experimental gas pair, which makes up 99% of the atmospheric composition, and hence constitutes a near-binary system to which Fick's laws can be applicable.

The chamber, isolated from the sample mounted atop with the plate in the closed position (Fig. 2), is initially flushed with N_2 to make the air inside O_2 -free. The movable plate is then removed enabling the atmospheric O_2 to move into the chamber, while N_2 moves out to the atmosphere following their opposite concentration gradients. Using an oxygen sensor mounted on the chamber wall, the change in O_2 concentration is continuously monitored. An analytical solution is used to calculate the soil-gas diffusion coefficient under the predetermined boundary conditions.

Governing equation

Fig. 2 Schematic of the one-chamber apparatus for measuring soil-gas diffusion coefficient (right) and initial and boundary conditions (left).

Assuming the soil is non-reactive (physically, chemically, and biologically) within the experimental timeframe (i.e., the retardation factor = 1);

$$\frac{\partial c}{\partial t} = \frac{D_p}{\varepsilon} \frac{\partial^2 c}{\partial x^2} \quad (11)$$

Initial and boundary conditions

$$C(x = 0, t \geq 0) = C_s$$

$$C(0 < x < L, t = 0) = C_s$$

$$C(L < x < L + a, t = 0) = C_s$$

$$C(L < x < L + a, t > 0) = f(t)$$

Analytical solution

$$\frac{C - C_s}{C_o - C_s} = \sum_{n=1}^{\infty} \frac{2h \exp(-D_p \alpha_n^2 t / \varepsilon)}{L(\alpha_n^2 + h^2) + h} \quad (12)$$

At some time greater than zero, terms with $n \geq 2$ become negligible with respect to the first term, and the equation reduces to,

$$\frac{C - C_s}{C_o - C_s} = \frac{2h \exp(-D_p \alpha_1^2 t / \varepsilon)}{L(\alpha_1^2 + h^2) + h} \quad (13)$$

where ε the air content ($\text{m}^3 \text{m}^{-3}$), L is the sample height (m), and h is the chamber height (m). Herein, α_1 is the positive root of α in the equation;

$$\alpha L \tan \alpha L = hL$$

The gradient of the C vs. t plot becomes linear in sufficiently large time, and the D_p can be calculated from the gradient $(-D_p \alpha_1^2 / \varepsilon)$. Detailed information can be found in [Rolston and Moldrup \(2002\)](#).

Modeling soil-gas diffusion

Similar to solute diffusion, laboratory measurement of the soil-gas diffusion coefficient is difficult and is often challenged by gas leaks through joints and valves, fine cracks in chamber materials, or misalignments in the sliding plate, just to name a few. Models often offer a quick and convenient alternative, provided that an adequate accuracy can be achieved. They are generally based on easily measurable soil physical properties such as air-filled porosity (ε) and total porosity (Φ).

The pioneering work on modeling soil-gas diffusivity dates back to 1904 when Edgar Buckingham developed a simple yet powerful model (Eq. 14; Buckingham, 1904) which stands even today amid an extensive series of diffusivity models developed over the last century.

$$\frac{D_p}{D_{o,g}} = \varepsilon^2 \quad (14)$$

The power exponent 2 in the Buckingham model makes it principally related to the analogous transport models, and hence provides a universal expression for soil-gas diffusivity ($D_p/D_{o,g}$). A series of power-law models subsequently appeared with different power exponents, e.g., 3/2 (Marshall, 1959), 4/3 (Millington, 1959). The Millington and Quirk (1961) model is presently the most widely used model predicting soil-gas diffusivity, despite not being originally derived for gas diffusion modeling.

$$\frac{D_p}{D_{o,g}} = \left(\frac{\varepsilon^{10}}{\Phi^2} \right) \quad (15)$$

Notably, this model performs better in structureless sands compared to silty and clayey soils. Several conceptual predictive models appeared subsequently (e.g., Troeh et al., 1982; Moldrup et al., 2000). The Troeh et al. (1982) model takes the form of

$$\frac{D_p}{D_{o,g}} = \left(\frac{\varepsilon - u}{1 - u} \right)^v \quad u < \varepsilon < 1 \quad (16)$$

where u and v are fitting coefficients in Eq. (16). The parameter u represents the air content below which gas diffusion ceases due to the disconnected air phase, caused by moisture-induced or compaction-induced pore discontinuity. Eq. (16) is comparable with Eq. (10a) discussed above in relation to solute diffusion. The parameter u represents a gas percolation threshold that can be described within the framework of percolation theory.

Across a broader array of soil textures, the water-induced linear reduction (WLR)-Marshall model (Eq. 17; Moldrup et al., 2000) was found to perform well for sieved-and-repacked soils.

$$\frac{D_p}{D_{o,g}} = \varepsilon^{1.5} \left(\frac{\varepsilon}{\Phi} \right) \quad (17)$$

However, since the conceptual development of the model (Eq. 17) does not account for the properties inherent to undisturbed soils (e.g., soil heterogeneity, layering, soil density variations), the model tends to overpredict the measurements in structurally undisturbed soils. To account for density across a broad range of undisturbed soils, Chamindu Deepagoda et al. (2011) introduced the so-called density-corrected gas diffusivity model:

$$\frac{D_p}{D_{o,g}} = 0.1 \left(2 \left(\frac{\varepsilon}{\Phi} \right)^3 + 0.04 \frac{\varepsilon}{\Phi} \right) \quad (18)$$

On a data-set of 280 intact soil samples, this empirically-based model performed better than existing models, but was still affected by complex soil structure. To improve predictions further, a media complexity factor, C_m was introduced to the WLR-Marshall model (Eq. 17) in the structure-dependent water-induced linear reduction (SWLR) model (Moldrup et al., 2013) (Eq. 19).

$$\frac{D_p}{D_{o,g}} = \varepsilon^{(1 + C_m \Phi)} \left(\frac{\varepsilon}{\Phi} \right) \quad (19)$$

The model provides excellent predictions due to its flexibility to represent different structure status by assigning different C_m values for repacked ($C_m = 1.0$) and undisturbed ($C_m = 2.1$) soils.

A scatterplot comparison of the performance of selected predictive models against undisturbed Danish soil data is illustrated in Fig. 3.

Unified modeling approach for solute and gas diffusion in soil

Considering the strong analogy of diffusive transport processes in soil-aqueous and soil-gaseous phases, both can be described in a unified mathematical framework. Diffusive transport in aqueous and gaseous phases is controlled by the fluid content and the tortuosity of the associated pore network. The analogy between gas and solute diffusion processes for structureless porous media (e.g. sand) has been demonstrated by Hamamoto et al. (2010). However, the gas phase tortuosity was mainly controlled by the fluid-phase (air) content and total porosity (i.e., by soil moisture conditions and soil compaction), while soil type (texture) was an additional major control of the liquid-phase tortuosity. Therefore, for silty and clayey soils, higher soil surface area attributed to higher fines contents reduced water layer coating soil particles, forming more tortuous water-filled pore networks. Unified predictive models combining soil-gas and solute diffusion coefficients have been proposed in past studies (Hamamoto et al., 2010, 2012). Hamamoto et al. (2012) introduced the Liquid and Gas diffusivity (LIGA) model;

Fig. 3 Scatterplot comparison of four predictive gas diffusivity models tested against 150 undisturbed soil data. MQ, Millington and Quirk; WLR, Water-induced linear reduction; SWLR, Structure-dependent water-induced linear reduction. Modified from Chamindu Deepagoda TTK, Moldrup P, and Schjønning P et al. (2011) Density-corrected models for gas diffusivity and air permeability in unsaturated soil. *Vadose Zone Journal* 10: 226–238.

$$\frac{D_i}{D_{o,i}} = \left\{ \frac{(\kappa - \kappa_{th})}{2 - (\kappa - \kappa_{th})} \right\} \left(\frac{\kappa - \kappa_{th}}{\Phi - \kappa_{th}} \right) \quad (20)$$

where subscript i indicates s for solute diffusion coefficient or g for gas diffusion coefficient. κ is the fluid content defined as a soil–air content (ϵ , $\text{m}^3 \text{m}^{-3}$) for $D_{s,g}$ and soil–water content (θ , $\text{m}^3 \text{m}^{-3}$) for $D_{s,l}$, respectively. κ_{th} is the percolation threshold ($\text{m}^3 \text{m}^{-3}$) defined as;

$$\begin{aligned} \kappa_{th} &= 0.11\Phi^4 \quad \text{for } D_g \\ \kappa_{th} &= P \times \text{FINES}_{vol} \quad \text{for } D_g \end{aligned}$$

where P is a constant, suggested as 0.6 in Hamamoto et al. (2012). FINES_{vol} is defined as the volumetric content of fines (including clay and organic matter). Nevertheless, such attempts to develop unified diffusivity models for soil are still at the preliminary stages and require broader experimental and numerical involvements in the future.

Concluding remarks

Accurate characterization of diffusion-controlled processes in soil–aqueous and soil–gaseous phases is essential to understand the important roles they play in regulating overall soil ecosystem health. It further provides useful implications to develop best

engineering practices to control related environmental problems, for example cleanup of contaminated sites, management of engineered landfills, etc. Further developments in experimental and computational capabilities will be highly beneficial to better characterize diffusion processes in soils and other environmental domains. Future computational attempts may put further emphasis on integrating both solute and gas diffusion modeling into a unified mathematic framework by means of universal scaling parameters.

Abstract

The movement of water in the subsurface, “Hydrodynamics,” touches many areas of the natural and human-influenced world. Ecosystems are shaped, contaminants spread, valleys flood, and slopes fail, all under the influence of hydrodynamic processes. These processes can be divided into four main subtopics based on whether flow is constant or changing in time and on whether the pores are or are not entirely filled with water. While these conditions share underlying concepts, there are specific considerations that make each unique.

Glossary

Richardson-Richards’ Equation A simplification of the coupled flow equations describing the movement of air and water through the same medium based on an assumption that air is infinitely mobile. This is commonly applied for soil physics and hydrology problems.

Saturated A condition under which all of the pores are filled with water. In some cases, immobile, trapped air is allowed and the condition is deemed “effective saturation.”

Steady-state A condition under which there are no changes in the state of the system with time; this includes both hydrostatic and non-zero flow conditions.

Storage The volume of water present in a given volume of porous medium.

Transient A condition under which there is a change in state of the system at any location; this only includes flowing conditions, but it may be limited to internal redistribution.

Unsaturated A condition under which the pores are filled with more than one fluid, often air and water.

Dynamic viscosity Dynamic viscosity is the resistance of internal shear of a fluid.

Flux The flow of a liquid per unit cross sectional area perpendicular to flow, [m s^{-1}].

Hydraulic conductivity The ease with which water can move through a porous medium under a given gradient, which depends on the pore structure, the fluid properties, and the volumetric water content, [$\text{m}^3 \text{m}^{-3}$].

Permeability The ease with which any fluid can move through a porous medium under a given gradient, which depends on the pore structure and the volumetric content of the fluid, [$\text{m}^3 \text{m}^{-3}$].

Pressure head The gage (relative to atmospheric) pressure of water divided by the weight of water, [m].

Specific storage A property of the medium and the fluid that describes the ability of a unit volume of medium to change the volume of stored water, while remaining fully saturated, per unit change in pressure head.

Specific yield A property of the medium and the fluid that describes the ability of a unit area (plan view) of medium to change the volume of stored water by drainage per unit change in pressure head at every depth.

Key points

- Flow occurs in response to an applied energy gradient in space;
- Steady-state flow through a homogeneous, saturated medium leads to a linear trend in hydraulic head with distance;
- The primary storage mechanism in a saturated medium, medium compaction, provides little storage capacity, so transient changes propagate relatively quickly;
- Steady-state flow through an unsaturated porous medium may give rise to changes in water content with distance, which leads to spatial variation in hydraulic conductivity, resulting in nonlinear trends in hydraulic head with distance; and

- Propagation of applied changes via transient flow through a variably saturated medium can be significantly more delayed than through a saturated medium because of the larger storage changes associated with changes in water content with time.

Nomenclature

K	Hydraulic conductivity [m s^{-1}]
k	Permeability [m^2]
q	Flux
Ss	Specific storage
Sy	Specific yield
μ	Dynamic viscosity ($\text{kg m}^{-1} \text{s}^{-1}$)
ψ	Pressure head [m]

Introduction

Hydrodynamics is, literally, the movement of water. Whereas hydrostatics can describe the distribution of water in a medium when it is not flowing, hydrodynamics describes how water flows and how that flow changes in time. As such, an understanding of hydrodynamics is fundamental to topics ranging from plant growth, to soil conservation, to construction, to weather prediction. Fluid flow always occurs due to a spatial energy gradient. However, the specific conditions give rise to very different descriptions of flow. As a result, soil-water dynamics can be subdivided into flow through a water-saturated or unsaturated medium, and under steady-state (constant in time) or transient conditions. Groundwater flow problems typically consider only saturated flow. Flow through the vadose zone requires study of flow through variably saturated media.

Steady-state flow through a saturated medium

The Darcy equation describes the response of a fluid in a porous medium to an imposed energy gradient. This simple formula, equivalent to Ohm's Law for electrical flow, forms the foundation of discussions of hydrodynamics. The one-dimensional form of the Darcy equation can be written as:

$$Q = -k \frac{\rho g}{\mu} A \frac{d(\psi + z)}{dL} \quad (1)$$

where Q is the flow ($\text{m}^3 \text{s}^{-1}$), A is the cross-sectional area perpendicular to flow (m^2), k is the intrinsic permeability (m^2), ρ is the fluid density (kg m^{-3}), g is the acceleration due to gravity (ms^{-2}), μ is the dynamic viscosity of the fluid ($\text{kg m}^{-1} \text{s}^{-1}$), ψ is the pressure head (m), z is the elevation (m), and L is the distance in the direction of flow (m) (note that the "head formulation" is used commonly to describe water flow. This is defined as the potential energy per unit weight of fluid. It is used widely because its units, length, are convenient for both laboratory and field applications. In the formulation, the influence of gravity is referred to as the elevation head and it acts only in the vertical direction.) The negative sign is necessary due to the definition of a gradient to define flow as occurring from a region of higher energy to lower energy. This can be rewritten in terms of the flux, $q(\text{ms}^{-1})$ as:

$$q = \frac{Q}{A} = -k \frac{\rho g}{\mu} \frac{d(\psi + z)}{dL} \quad (2)$$

Flow occurs in the direction of decreasing energy of the fluid, and the rate of flow depends directly upon the ability of the medium to permit flow (permeability), the fluid density, and the acceleration due to gravity, and inversely upon the resistance of the fluid to internal deformation (dynamic viscosity). Introducing the hydraulic conductivity, $K (\text{ms}^{-1})$ allows simplification to:

$$Q = -KA \frac{d(\psi + z)}{dL} \quad (3)$$

Considering flow in the horizontal, x -direction, the flux density is:

$$q_x = -K \frac{d(\psi + z)}{dx} = -K \frac{d\psi}{dx} \quad (4)$$

This indicates that horizontal flow is driven only by pressure head gradients. The flux density for flow in the vertical, z -direction, is:

$$q_z = -K \frac{d(\psi + z)}{dz} = -K \left(\frac{d\psi}{dz} + 1 \right) \quad (5)$$

Fig. 1 Pressure-head profiles along a horizontal column during steady-state saturated flow. Note that the hydraulic head is equivalent to the pressure head if we assume that the center height of the column is located at $z = 0$.

This shows that vertical flow is driven by both gravity and pressure gradients. Note further that the hydraulic conductivity may be different in the horizontal and vertical directions, for example due to layering caused by depositional processes (known as anisotropic conditions).

As a baseline, it is useful to know how the pressure head, elevation head, and hydraulic head are distributed within homogeneous systems (K does not vary with location) undergoing steady state flow. Fig. 1 shows a horizontal column of uniform cross-sectional area. The elevation head is constant everywhere. The pressure and hydraulic head gradients must be constant with x location to achieve steady state conditions. If this were not the case, then there would be more flow into some regions than out of those regions, which would cause the amount of water in storage to change with time, violating the steady state assumption. This is shown for a 200-cm-long, homogeneous horizontal column for which the left boundary is maintained at a constant pressure head of 70 cm and the right boundary is held at a constant pressure head of 0 cm (top panel, Fig. 1).

The two-dimensional form of the Darcy equation follows directly from the one-dimensional form. For instance, two-dimensional flow in the x - z plane is described as:

$$q_i = -K_{ij} \frac{d(\psi + z)}{dx_j} \quad (6)$$

This equation includes the term K_{ij} , which can be read as “the conductivity in the i -direction due to a gradient in the j -direction.” The derivative term describes the head gradient in the j -direction.

Transient flow through a saturated medium

It can be confusing to learn that a medium can be saturated while also experiencing a change in water stored with time. This occurs through two transient processes in response to a change in the water pressure: a change in the porosity, and a change in water density. The former occurs because water that resides in a medium under a positive pressure head acts to expand the matrix of the

medium, essentially pushing the soil grains apart. If the water pressure is reduced, the effective stress on the medium will increase and the medium will compact. By compacting, the porosity of the medium is reduced as water is released from storage while maintaining full water saturation. Simultaneously, the decreased pressure of the water allows the water itself to expand, thereby occupying more volume per unit mass of water. However, this expansion of water is negligibly small for most water flow problems. These two processes combined are referred to as the specific storage of a medium. This lumped property is critical to understanding the transient response of a saturated porous medium.

To describe transient flow in a water saturated medium, we begin with Eq. (6), which describes flow in response to a gradient. Consider the three-dimensional region shown in Fig. 2. Each edge has a constant length, ΔL . Flow is two-dimensional in the x - z plane. At steady state the sum of q_x in and q_z in will be equal and opposite to the sum of q_x out and q_z out, and there won't be any change in water stored with time. However, under transient flow conditions, these sums will not be equal. The net difference in the inflow and the outflow will equal the change in the volume of water stored, ΔV_w , per unit time elapsed, Δt , per unit area of the region. This is written as a mass balance equation:

$$dQ_x + dQ_z = \frac{dV_w}{dt} \quad (7)$$

For simplicity, we assume that all sides of the box have the same size, $dx = dy = dz$. Dividing by the volume of the box gives:

$$\frac{dq_x}{dx} + \frac{dq_z}{dz} = \frac{dV_w}{(dxdydz)dt} \quad (8)$$

We can then describe the change in volume of water per volume of the box as the change in porosity as a function of the change in pressure head, which is approximately equal to the specific storage, S_s [L^{-1}]. This leads to the flow equation:

$$\int \frac{dq_i}{dx_i} dx_i = S_s \int \frac{d\psi}{dt} dt \quad (9)$$

In words, this states that the divergence of the flow is equal to the change in storage with time.

Given the flow equation, consider what would happen in the column shown in Fig. 1 if the pressure head on the left boundary was increased instantaneously. The gradient would increase at the left boundary, causing more water to flow into the column. The increase in pressure would increase the water storage, so some of this increased flow would be added to storage and less of it would remain to flow farther to the right. As a result, the storage mechanism acts to slow the propagation of the change in pressure head imposed at the right boundary. Eventually, a new steady state condition would be established with a steeper left-to-right gradient and more water stored within the column. In reality, the storage capacity of a saturated medium is very small, so the transient period would be relatively short. If these processes are scaled up to field-relevant distances, however, the delays due to transient flow can last for days, months, or even centuries!

To visualize transient, saturated flow, consider a transition between two steady-state conditions (Fig. 1, bottom panel). The solid line shows the steady state conditions discussed earlier. The lowest, dotted line relates to steady state flow with a lower head on the left boundary. The dashed lines show the transition between these two steady state conditions. Note that the change occurs at the left boundary first (the topmost dashed line) and then propagates farther to the right with increasing time. At early time, there is no change in the outflow from the right boundary, even though the left boundary condition has changed. The transient profiles are nonlinear, even for saturated flow, indicating that flow into and out of any volume of porous medium are not equal. This leads to a change in storage, and therefore a change in the head, with time.

Fig. 2 Three-dimensional unit cell for consideration of conservation of mass. The flux density into (q in) and out of (q out) the cell is shown in the x and z directions only for clarity.

Steady-state flow through an unsaturated medium

The Darcy equation is equally applicable to steady-state flow through both saturated and unsaturated media. However, there is a critical difference when this relationship is applied to unsaturated flow. Specifically, the hydraulic conductivity (or intrinsic permeability) of the medium varies with the pressure head of the water in the medium. More accurately, the hydraulic conductivity depends on the water content (the fraction of the pores that are filled with water), because water only flows through water-filled pores under steady state conditions. As the water pressure decreases below atmospheric pressure, air can invade soil pores. Due to capillarity, the largest pores allow air to enter at higher water pressures. As a result, these pores, which contribute the most to the overall hydraulic conductivity, drain at higher (less negative) pressure. This leads to a very rapid decrease in hydraulic conductivity as a medium transitions from full to partial saturation. The equation describing unsaturated flow is deceptively simple:

$$q_i = -K_{ij}(\theta) \frac{d(\psi + z)}{dx_j} \quad (10)$$

where θ is the volumetric water content $[-]$, defined as the volume of water in a given total volume of medium.

The ramifications of the dependence of the hydraulic conductivity on the volumetric water content can be quite dramatic. For example, consider the case of steady-state, one-dimensional, horizontal flow through a homogeneous medium, such as shown for saturated conditions in Fig. 1. The pressure-head profile is shown in Fig. 3 for a 200-cm-long, sand-filled column with the left boundary held at a constant pressure head of 0 cm and the right boundary held at a constant pressure head of -70 cm. Notice that, unlike the case of steady-state one-dimensional flow through a saturated medium, the pressure head varies nonlinearly in the direction of flow. This occurs because the hydraulic conductivity decreases steadily with decreasing pressure head from the saturated value at the left boundary to a much lower value at the right boundary. To maintain steady-state flow throughout the column, the magnitude of the gradient must increase to compensate for this decreasing hydraulic conductivity. Therein lies the difficulty of calculating the pressure-head distribution during unsaturated flow. Even under the apparently simple conditions of steady-state, one-dimensional horizontal flow, the pressure-head distribution depends on the hydraulic conductivity distribution, which depends on the pressure head distribution. This “circular” dependence describes a nonlinear condition.

Fig. 3 Pressure-head profiles along a horizontal column during steady-state unsaturated flow.

Transient flow through an unsaturated medium

Transient unsaturated flow is fundamentally different than saturated flow and steady-state unsaturated flow. During transient unsaturated flow, water enters pores that were previously occupied by air (or air enters previously water-filled pores). If we assume that the air can move easily, such that it does not impede the movement of water, the flow of water can be defined using only one equation—the Richardson-Richards' equation (Eq. 10). In addition to the nonlinear nature of unsaturated flow, as shown in Fig. 3, the mechanism of storage results in far greater storage capacity. That is, you can change the volumetric water content by much more than you can change the porosity by changing the water pressure. Remembering that changes in storage act to slow the propagation of a change applied to a system (e.g., the change in the pressure at the left boundary discussed above), we can expect that transient conditions have much more impact on flow under unsaturated conditions.

Transient, unsaturated flow appears qualitatively similar to transient saturated flow (Fig. 3, bottom panel). Both steady state profiles are nonlinear, as discussed above. But, as for saturated conditions, the change occurs at the left boundary first (the topmost dashed line) and then propagates farther to the right with increasing time. There is a similar period during which there is no change in the outflow from the right boundary, even though the left boundary condition has changed. Because of the storage mechanism, filling and draining of the pores, leads to much larger changes in storage than the corresponding mechanisms under saturated conditions, transient conditions propagate more slowly through unsaturated soils. This increased time is magnified by lower hydraulic conductivity of the partially saturated soils.

Conclusions

The flow of water through porous media is critical to many fields of study in natural science and engineering. A basic understanding of the underlying processes, such as is presented here, is relatively accessible. But, understanding how water moves through a complex, transient system requires experience and the help of computer models. Specific models are constructed to examine how multiple fluids move and interact at the scale of a few soil pores. Other models track water movement from the atmosphere to the deep subsurface at the scale of the entire Earth. Still other models are built to predict the impacts of changes in irrigation practices, water extraction for municipal use, or land cover change at every intermediate scale. Each of these applications of hydrodynamics requires supporting data and nuanced understanding of water movement and storage to fully capture the many roles of water in the environment.

Abstract

The fundamentals of thermodynamics are applied to soil water. The first part deals with equilibrium (classical) thermodynamics. The essential point is the mathematical expression for the chemical potential of soil water. The second part deals with non-equilibrium (irreversible) thermodynamics. The key element is the development of a mathematical expression for the total energy dissipation (entropy production), taking into account all possible transport processes (entropy producing phenomena) occurring in the chosen “system.” This expression is then used to construct transport equations for all those transport processes. Each transport equation contains a flux as a linear function of all possible driving forces. In this scheme all possible Onsager Reciprocal Relations are exposed in the symmetric matrix of transport coefficients.

Key points

- Thermodynamics applied to soil physical processes of heat, solute and mass transfer is described.
- The article builds from the origins of thermodynamics as a discipline to its application to soil science.
- Processes described for soil occur not far from equilibrium, such as Darcy’s Law, but some catastrophic processes in soil may benefit from recent developments in Non-linear Non-equilibrium Thermodynamics.

Introduction

The word thermodynamics is derived from the ancient Greek words for heat, $\theta\epsilon\rho\mu\omicron\varsigma$, and force or power, $\delta\upsilon\nu\alpha\mu\iota\varsigma$. It presents the science of all forms of energy and mass, including entropic (“waste”) heat contained in the mass at ambient temperature. The origin of the word suggests that this branch of science deals with both the statics (equilibrium) and the dynamics (non-equilibrium) of energy and mass. Statics (“Classical Thermodynamics”) deals with the state of the system in which no heat or mass transfer occurs (this state is extremely rare in natural soils). Dynamics (“Non-equilibrium Thermodynamics”) deals with transport processes of mass and heat. “Soil water” is often used interchangeably with the term “soil moisture.” Here we distinguish between the two terms:

[†] Author deceased.

“soil water” indicating the chemical component H_2O in the soil and “soil moisture” meaning the soil solution. Thermodynamics distinguishes the different chemical components in the system. It deals with the interaction between and transfer of these components and heat.

Classical (equilibrium) thermodynamics of soil water

The birth of thermodynamics is rather confusing. The founders tried to deal with such things as the effectiveness of steam engines (S. Carnot). R Meyer, who was the first (1842) to publish the equivalence of work and heat, based his conclusion on his observations of the degree of “redness” of human blood. No wonder that thermodynamics had a shaky start. The first mathematical formulation of the “First Law of Thermodynamics” (the law of conservation of energy) came from Helmholtz and Joule in 1847. All these scientists were dealing with systems, which were “on the move.” Yet the system had to be at equilibrium and the “changes” had to be infinitesimally small and “reversible” (meaning that the changes can be reversed without any loss of useful energy at the ambient temperature, or entropy production). An excellent overview of these matters can be found in Pippard’s book (Pippard, 1964).

One would expect the First Law of thermodynamics to equate integral values of the different forms of energy. Yet the equations always come in differential form first. At first only “closed” systems were considered, implying that no mass could move into or out of the “system.” It was not until J. Willard Gibbs, 1876, 1878 published his two great treatises “The Equilibrium of Heterogeneous Substances” (Gibbs, 1876, 1878), that the “system” was opened up and many of the mysteries of the previous 50 years were clarified. The Transactions of the Connecticut Academy were not widely read in Europe and it was not until G.N. Lewis published his famous book in 1923, 20 years after Gibbs’ death, that his works became widely known. In the year of his retirement, Gibbs remarked that during the 30 years of his teaching at Yale University, he estimated that only half a dozen of his students had benefited from his lectures (Gibbs, 1961), which were published some 58 years after his death.

Physicists, like Maxwell and Einstein, immediately recognized the intrinsic value of Gibbs’s work. Chemists and, in particular, scientists in applied disciplines were much slower to accept and understand Gibbs’s work. In the field of Soil Science, the pioneers were Edlefsen and Anderson (1943). Closer to home, it was Cary (1963, 1964) who brought Irreversible Thermodynamics into Soil Physics. Cary concentrated his work on the coupled transport process called thermo-osmosis.

We start with the integrated Gibbs Equation:

$$E = U + \Psi = TS - PV + \sum_i \mu_i m_i + \sum_i \psi m_i \quad (1)$$

where E is the energy of the system, U is the “internal” energy, and Ψ is the sum of the “free” energy contained in the components of the system and the energy derived from external force fields, e.g. the gravity force ($\psi = gh$).

U consists of three “blobs” of different forms of energy, the first one (TS) being the entropic energy (heat in the system at the ambient temperature, T), the second one ($-PV$) being the energy the system has lost in order to create a volume, V , for itself to exist at the ambient pressure, P , the third one being the sum of the chemical energy of each component (i) in the system, with m_i being the mass of component i and μ_i being the chemical potential of component i .

Ψ is derived from external force fields, such as gravity or an electrical or magnetic field (in the gravity field $\psi = gh$, g being the gravitational acceleration and h the height above the reference level). If other forms of energy (such as kinetic energy or viscous stress energy) play a role in the transformations of energy, they should be added to Eq. (1). Although kinetic and viscous stress energy play a dominant role in energy transformations in the soil solution on the Navier-Stokes scale, on the Darcy scale they are almost always negligible, and will therefore be ignored here.

“Gibbs” energy, G , is defined by

$$G \equiv U - TS + PV = \sum_i \mu_i m_i \quad (2)$$

Thus, μ_i is the specific (per unit mass) Gibbs free energy of constituent i .

The first expressions of the First Law were all in differential form, even after Gibbs “opened up” the system:

$$dU = TdS - PdV + \sum_i \mu_i dm_i \quad (3)$$

When Eq. (3) is combined with the total (mathematical) derivation of Eq. (2), the result is:

$$SdT - VdP + \sum_i m_i d\mu_i = 0 \quad (4)$$

This “left-over” is known as the Gibbs-Duhem equation.

From Eq. (4) it follows that

$$d\mu_w = -Sm_w^{-1}dT + Vm_w^{-1}dP - \sum_{(k \neq w)} m_k m_w^{-1} d\mu_k \quad (5)$$

The last term of Eq. (5) represents the concentration dependent part of $d\mu_w$.

This is the central equation in equilibrium thermodynamics of soil water (Groenevelt and Bolt, 1969). The pressure term contains all surface tension effects. This expression is used to formulate the driving force in Darcy’s law and subsequently the non-conjugated driving forces in the thermodynamic transport equation for the soil solution.

The guiding principle is now, that when the system is in equilibrium, $d\mu_w = 0$, or, the specific Gibbs free energy of water is the same everywhere, or, as far as water is concerned, there is no transport and no entropy production. In short: the water is at rest. The inverse statement: “when $d\mu_w = 0$, the water is at rest” is not necessarily true and is not a fundamental principle of thermodynamics. It is possible that the last two terms of the RHS of Eq. (5) (temporarily) balance each other, making $d\mu_w = 0$, but both water and the solute are on the move, and entropy is being produced. This is possible when “leaky” semi-permeable membranes are present. Heavy clay soils are excellent examples of “leaky” semi-permeable membranes.

Therefore, the concept of the “total” potential of the soil water (the sum of all the component potentials) is not very useful. When the whole system is at rest (complete equilibrium), then the total potential of the water is equal everywhere in the system.

But, when the total potential of the water is equal everywhere, this does not necessarily mean that the water is at rest. The gradient of the total potential is not the appropriate driving force in the flux equation of water. This will become clearer in the section on non-equilibrium thermodynamics.

The apprentice in thermodynamics often asks him/herself: “What is the practical use of all this?” Thermodynamics is still not a coherent, comprehensive science. Developments are still happening haphazardly. Some scientists, like the American mathematician Clifford Truesdell, complained bitterly about the inconsistencies and the lack of mathematical rigor, using words like “thermodynamics was approached through detours in the fog of word-play.”

Here, only two of the practically useful results will be discussed:

The tensiometer (and the pressure membrane apparatus)

Early scientists, working on the thermodynamics of soil moisture, such as L. A. Richards, G. H. Bolt and M. J. Frissel (1960), immediately realized that water in the soil is present in the soil solution and that the soil solution is never pure water. The soil solution contains dissolved salts and ions. In addition, it contains counter-ions, that is a surplus of cations, necessary to counter-balance the surplus of electrons present in the lattices of clay particles. The electrical double layer acts as an osmometer and the counter-ions cause a volume element of the solution, close to a clay surface, to carry a volume charge. This gives the soil solution an additional opportunity to possess energy (in the presence of an electrical field). In addition to the above, there are micro-force fields acting on the solution that is in close proximity of solid surfaces (London-Van der Waals forces). All this implies that Eq. (5) should contain a few more terms if the thermodynamic system were chosen on the Navier-Stokes scale.

The first requirement in Soil Physics is to formulate and assess the hydrostatics of soil water, i.e., establish the characteristic relationships when the water is at rest. There are no “membranes” in nature or in the laboratory that are semi-permeable to heat. Thus, when a system is brought to equilibrium the temperature will be the same everywhere. The energy level in the external force fields, such as gravity, can easily be established separately. To measure the energy level of soil water derived from internal force fields (menisci, electrical double layers, London-Van der Waals forces), it is now advantageous to bring the soil solution in equilibrium with either a compartment containing a solution that reflects the composition of the soil solution or one that contains pure water. There are membranes that are (“perfectly”) semi-permeable to all dissolved materials in the soil solution. In the latter case (using a perfect osmometer and measuring the hydrostatic pressure in the osmometer with respect to atmospheric pressure), one measures the energy level of the soil water at the ambient temperature and at the particular position in the external force field, resulting from all internal force fields plus all dissolved materials (the total osmotic pressure of the soil solution). In the former case, using a perfectly “leaky” membrane, such as a sintered ceramic cup (tensiometer cup) or a Visking membrane in a pressure plate apparatus, the solution inside the compartment (tensiometer cup) will reflect the composition of the “free salts” in the soil solution and will show the “equilibrium” solution. By measuring the hydrostatic pressure in a tensiometer with respect to atmospheric pressure, one measures the energy level of all internal force fields (including electrical double layers), but excluding the free salt. This energy level is called the matric potential. The counter-ions cannot equilibrate in the tensiometer cup. They act as internal mini-osmometers and can be considered part of the matrix (the solid phase of the soil). Because most soils are pretty “leaky” as far as the exclusion of dissolved materials is concerned, the water in the soil moves largely as a solution. It is therefore the gradient of the matric potential that is the dominant driving force on the soil water (in addition to the force of the gravitational field). The imperfect semi-permeability of a clay soil, causing osmotic pressure differences to drive the water, will be dealt with in the section “Non-equilibrium thermodynamics” (see below). The action of osmotic pressure gradients will then be formulated as “capillary” osmosis and the imperfect semi-permeability will be evaluated by the “reflection coefficient.”

The Maxwell relations and their use in the hydrostatics of swelling soils

Before entering the field of non-equilibrium states (entropy production), it is useful to pay attention to the Maxwell relations. Here, one is crossing the border area between classical and irreversible thermodynamics. In equilibrium thermodynamics, the temperature and pressure were allowed to change but only in very small steps, δT and δP . Entropy production was not allowed. It began to look like differentiation, but differentiating with respect to what? Time or space? Once the independent variable is chosen (i.e., space), the driving forces for the transport processes can be formulated. Applying cross-differentiation in the matrix of driving forces, one obtains the Maxwell relations.

As a prime example of the use of a Maxwell relation we present here the following. For many decades soil scientists have searched for an expression for the differential of the matric potential (tensiometer pressure), p , with respect to the load (or overburden pressure), P , at constant ratio of mass of water and mass of solids. Here, both the dependent and the independent variable are

intensive variables. The appropriate Maxwell relation shows that the above differential is equal to the differential relationship between the void ratio (volume of voids per volume of solids), e , and the moisture ratio (volume of water per volume of solids) at constant load pressure, P . Here, both the dependent and the independent variables are extensive variables (Groenevelt and Bolt, 1972).

Thus:

$$dp(dP)^{-1} \text{ at constant } m_w(m_{\text{solids}})^{-1} = de(d\vartheta)^{-1} \text{ at constant } P \quad (6)$$

where p = the tensiometer pressure, P = the load pressure, e = the void ratio and ϑ = the moisture ratio (volume of water per volume of solids) at constant load pressure, P .

This means that one can predict the behavior of the tensiometer reading upon loading from the slopes of the shrinkage lines for different values of P . Because the shrinkage lines for different values of P are nearly parallel, one only needs to measure the unloaded shrinkage line to predict how the tensiometer reading changes when moving deeper into the soil profile or upon loading by machinery.

Non-equilibrium thermodynamics of soil water

The thermodynamic “system” is now chosen to be a unit volume element in the soil solution. All the extensive variables are expressed per unit volume. Subsequently, each of the terms of the differential form of the Gibbs equation (Eq. 3) are written as differentials with respect to time.

The mathematical sloppiness of classical thermodynamics disappears once the terms of the differential form of the Gibbs equations are transformed into proper time differentials and one enters the realm of non-equilibrium thermodynamics.

Next, for each of the terms separately, an appropriate conservation (continuity) equation is constructed. The general form of such a conservation equation shows that the change of the content of the entity of concern, with time, is equal to the negative of the divergence of the flux of that entity (inflow minus outflow), plus or minus one or more source or sink terms. Thus, for the entropic energy term one writes:

$$d(SV^{-1}) dt^{-1} = -\text{div } j_s + \sigma \quad (7)$$

where SV^{-1} is the entropy per unit volume of solution; j_s is the flux of entropy and σ is the entropy production term. This latter term plays a central role in non-equilibrium thermodynamics. If all the processes and forms of energy are accounted for, and nothing is counted twice, and all algebra is carried out correctly, then the entropy production term is non-negative. As the absolute temperature is always positive, the energy dissipation term, $T\sigma$, must also be non-negative. When σ , and thus $T\sigma$, is zero, the system is at equilibrium and nothing moves. If anything moves, then entropy is produced, and σ and $T\sigma$ are positive. Energy is being dissipated. That is, energy is transformed from useful energy to waste energy (= heat at the ambient temperature). This is the “Second Law of Thermodynamics.”

As the first term on the RHS of Eq. (3) is already multiplied by T , one finds, after replacing the time differentials of the different terms in Eq. (3) by the RHS of their appropriate conservation equations, the product $T\sigma$ as the source term of the entropy conservation equation. After all the appropriate substitutions are made, the term $T\sigma$ is singled out (written explicitly) and the equation is then called “the (energy) dissipation function.”

On the RHS of the dissipation function one usually finds the sum of a number of products of fluxes and forces. One may reshuffle these forces and the fluxes, under the strict principles that the rules of algebra are carried out correctly and that nothing is forgotten or counted twice.

The resulting complete expression for the energy dissipation is then the sum of products of fluxes and conjugated forces.

$$T\sigma = -j_q \text{ grad } T - j^V \text{ grad } H - j^D \text{ grad } \pi - j^E \text{ grad } E \quad (8)$$

where j_q is the caloric (Fourier) heat flux; j^V is the (Darcy) flux of the soil solution; j^D is the (Fick) diffusion flux and j^E is the electric current (usually indicated by capital I).

$\text{grad } \pi$ is the gradient of the osmotic pressure and $\text{grad } E$ is the gradient of the electrostatic potential.

One recognizes the primary forms of dissipation, viz. the dissipation of heat energy, pressure energy, mixing or unmixing energy, and electrical energy.

If one now constructs simple linear homogeneous transport equations relating a flux to its conjugated flux (the one that is occurring in the same product), one gets, respectively, the transport equations of Fourier (1822), Darcy (1856), Fick (1855), and Ohm (1827).

Physics and Chemistry have long recognized that “coupled” transport can occur. Examples of such coupled transport processes are osmosis, electro-osmosis, thermo-osmosis and the Peltier effect. A coupled transport process takes place when a flux arises due to a non-conjugated force (that is a force that occurs in a product other than the one in which the flux of concern occurs).

Non-equilibrium thermodynamics now postulates that each flux, occurring in the energy dissipation function is a linear, homogeneous (no intercept) function of all forces occurring in the same equation for the total energy dissipation. Thus:

$$j_q = -L_{TT} \text{grad } T - L_{TV} \text{grad } H - L_{TD} \text{grad } \pi - L_{TE} \text{grad } E \quad (9)$$

$$j^V = -L_{VT} \text{grad } T - L_{VV} \text{grad } H - L_{VD} \text{grad } \pi - L_{VE} \text{grad } E \quad (10)$$

$$j^D = -L_{DT} \text{grad } T - L_{DV} \text{grad } H - L_{DD} \text{grad } \pi - L_{DE} \text{grad } E \quad (11)$$

$$j^E = -L_{ET} \text{grad } T - L_{EV} \text{grad } H - L_{ED} \text{grad } \pi - L_{EE} \text{grad } E \quad (12)$$

The diagonal (backward slash) terms of the right-hand sides of Eqs. (9)–(12), with the L_{KK} coefficients, represent the “straight”, well-known transport processes, and are known as the “laws” of Fourier (1822), Darcy (1856), Fick (1855), and Ohm (1827), respectively. All other (off-diagonal) terms represent coupling processes, and their coefficients, L_{KM} , are known as coupling coefficients. They come in pairs of twins, and are located symmetrically across the diagonal. They represent all possible coupling phenomena that can occur, in this case in the presence of the four driving forces occurring in this scheme.

If the energy dissipation equation is complete and all algebra has been carried out correctly, then the two twin coefficients are equal (Groenevelt, 1971):

$$L_{KM} = L_{MK}. \quad (13)$$

Thus the matrix of coefficients in Eqs. (9)–(12) is symmetrical. In the above matrix there are six of these pairs of equal twins. These equalities are known as the Onsager Reciprocal Relations (ORRs).

After the publication of his, now famous, papers, Onsager’s (1931a, 1931b) work received little attention, until, Miller (1960), working at the Lawrence Radiation Laboratory at the University of California in Livermore, Ca., under the auspices of the U.S. Atomic Energy Commission, published the results of a vast array of experiments trying to verify the ORRs. His conclusions were: “For thermoelectricity, electro-kinetics, isothermal diffusion, and anisotropic heat conduction, the experimental checks are sufficiently good that the validity of these relations is practically unquestionable,” and “In view of the above, the author concludes that the experimental evidence is overwhelmingly in favor of the validity of the Onsager reciprocal relations.”

Miller’s work has remained unknown in the field of Soil Physics for a long time and Onsager’s work has remained in doubt and sometimes ridiculed even after he was awarded the Nobel Prize (see the cartoon in the Saturday Review (1969, p.88) as reproduced in Groenevelt (1971)).

It was Elrick’s group of soil physicists that undertook the first thorough experiment concerning one of the coupled transport processes in the laboratory (Elrick et al., 1976).

To keep everything under complete control, they chose as “porous medium” homogeneous, homo-ionic montmorillonite, a fine clay, instead of real soil. The results, involving capillary osmosis and reverse osmosis, as well as electro-osmosis and streaming current, are presented in Groenevelt et al. (1978).

The fundamental value of the procedure outlined above is that all possible forms of energy dissipation are accounted for, even if they have never been observed.

For Soil Physics they are extremely important and useful (Groenevelt, 1971).

After the merciless denigration of the Onsager Reciprocal Relations by Truesdell (1968), soil physicists should rise up and accept the validity and the great practical usefulness of ORRs. The framework of the matrix of coefficients in Eqs. (9)–(12), is comparable, in nature but not quite in stature, to the periodic system as proposed by Mendeleev. For his systematic framework Onsager received the Nobel Prize in Chemistry (1968), which Mendeleev never received. The first such prize in chemistry was awarded to Jacobus van’t Hoff, even though Mendeleev was still alive. The refusal by the Nobel Committee to award the prize to Mendeleev continued until his death in 1907.

The framework makes it possible, in case the measurement of a certain coefficient is difficult or expensive, to measure its twin, which often appears to be easier or cheaper to measure.

When building models for transport processes in clay soils, e.g., based on electrical double layer theory, one can use these ORRs to verify the correctness of the model: if the cross-coefficients are not equal, the researcher can be assured that somewhere she or he made a mistake.

The actual occurrence of a coupled transport process always relies on some kind of a selection mechanism, such as a mechanism that can select between molecules of different chemical nature, e.g., water and salts, or a mechanism that can select between “hot” and “cold” molecules, e.g., a liquid-gas interface (Groenevelt and Elrick, 1976; Groenevelt and Kay, 1974). It should be noted that convection (advection) is never a selection mechanism.

The coupled transport processes are discussed here in pairs of twin phenomena, and indicated by their (equal) coefficients:

L_{TV} (thermo-filtration) and L_{VT} (thermo-osmosis)

Both these phenomena are very common in soils. The transport of heat due to a water potential gradient in the absence of a temperature gradient and the transport of water due to a temperature gradient in the absence of a water potential gradient are occurring constantly in the soil. In unsaturated soil they are due to evaporation and condensation [the selection mechanism here is the heat of vaporization or condensation]. In saturated soils the magnitude of these phenomena is very small [the selection mechanism is now the heat of wetting]. In frozen soils they are caused by freezing and melting [here, the selection mechanism is the heat of freezing or melting and solidification or sublimation].

These phenomena and the values of the two coefficients are discussed in the literature by Kay and Groenevelt (1974).

L_{TD} and L_{DT} (thermo-diffusive processes)

In the literature these phenomena are known as, respectively, the Dufour effect and the Soret effect (Mortimer and Eyring, 1980). The magnitude of these effects in soils is small, but their occurrence is quite probable.

L_{TE} and L_{ET} (thermo-electric processes)

In the literature these phenomena are known as, respectively, the Peltier (1834) effect and the Seebeck (1822) effect. The magnitude of these phenomena in soils is small, but their occurrence is quite likely.

L_{VD} (osmosis, also called capillary osmosis) and L_{DV} (reverse osmosis or salt sieving)

These phenomena are common in soils. The magnitude is directly related to the clay content of the soil. [The selection mechanism lies with the electrical double layer]. Clay particles expel negative ions and therefore, they expel dissociated salts (negative adsorption). The longstanding conflict as to whether the osmotic pressure (potential) should be added to the hydraulic potential of water to produce the “total” potential of water, the gradient of which then serves as the driving force on the water, is here resolved. As the value of L_{VD} is almost always smaller, than the value of L_{VV} (except for a perfectly semi-permeable membrane), the concept of the “total” potential is useless. The ratio L_{VD} over L_{VV} is known as the **reflection coefficient**.

L_{VE} (electro-osmosis) and L_{EV} (streaming current)

These electrokinetic phenomena also find their cause in the existence of electrical double layers. The most commonly observed result of the effects is the streaming potential in clay soils.

L_{DE} (electro-phoresis) and L_{ED} (diffusion current)

These phenomena, together with osmosis and reverse osmosis, electro-osmosis and streaming current are extensively discussed in the literature by Elrick et al. (1976) and Groenevelt and Elrick (1976). They calculated the magnitude of all six coefficients on the basis of electrical double layer theory.

The “linearity” argument

In his original theory, Onsager (1931a,b) stipulated that “the system” should be “close to equilibrium.” He was trying to wrestle the branch of science, Thermodynamics, out of the 19th century constraint that the system should be “closed” and at equilibrium. Ever since its publication up to the awarding of the Nobel Prize to Onsager in 1968, and long after that, the question has been raised: “How close is close to equilibrium?” Here, an argument to resolve this conundrum is as follows:

Onsager’s theory deals with the dissipation of energy (entropy production). There are many processes that dissipate energy. In Physics and Chemistry, the processes often carry the name of the scientist who formulated the process by means of an equation. Names, such as Fourier, Fick, Ohm, and Darcy, are examples of transport equations that are accompanied by energy dissipation. These equations contain a driving force which results in a flux. These two components are linearly and homogeneously related by a transport coefficient. When the driving force is zero, there is no flux and no energy dissipation: the system is at equilibrium. The driving force and the resulting flux are “conjugated.” The theory of Onsager deals with the energy dissipation during processes where the driving force and the flux are not “conjugated.” These processes are called “coupled transport processes” and carry names such as osmosis, thermo-osmosis, and electro-osmosis, or they carry the name of the first observer, such as “Dufour effect,” “Seebeck effect.” Onsager reasoned that each flux is also a linear homogeneous function of each non conjugated force that acts upon the system. In general, these non-conjugated relations are of a secondary intensity as the two related primary (conjugated) mechanisms of energy dissipation. By setting each flux as a homogeneous, linear function of each possible driving force, the set of transport coefficients appears as a matrix. Onsager’s “discovery” is now that this matrix is symmetrical, i.e., that each non-diagonal coefficient is equal to its counterpart on the other side of the diagonal:

$$L_{KM} = L_{MK} \quad (14)$$

The proposed solution for the conundrum now reads:

“As long as the primary (diagonal) process-behavior is homogeneous and linear, the secondary (non-diagonal) process must also be homogeneous and linear. So, as long as Darcy’s law holds (no turbulence in the soil water), one can be assured that the non-linear dissipation process is also linear.”

The general transport equations now formulate the different fluxes as the sum of a set of products of a driving force and a transport coefficient. These transport coefficients form a square matrix of which the diagonal elements represent the conjugated transport processes and the off-diagonal coefficients represent the non-conjugated (couple) transport processes.

The “discovery” by Onsager is now that the matrix of coefficients is symmetrical. Obviously, the requirement that the system should not be “too far from equilibrium” is linked to the linearity of the coupled transport processes, which, in turn, is subjugated by the linearity of the conjugated transport processes.

So, as long as the conjugated laws hold, e.g., Darcy’s law holds (no turbulence in the soil), the laws for non-conjugated transport processes (capillary-osmosis, thermos-osmosis and electro-osmosis) also must hold (Kay and Groenevelt, 1974).

Note: When Onsager received his Nobel prize for Chemistry in 1968, 37 years after he formulated the “Reciprocal Relations”:

$$L_{KM} = L_{MK} \quad (15)$$

the Nobel Committee obviously ignored Nobel’s stipulation that the prize should be awarded for recent work, a stipulation that prevented Mendeleev from receiving the prize because the work was “too old.” Onsager’s work is now 90 years old. A greater recognition in the sciences that deal with porous media such as soils and membranes is overdue (Katchalsky and Curran, 1965).

The thermodynamic versus the mechanistic theory

Apart from the thermodynamic theory for transport processes and their coupling, there is also a mechanistic theory (Hillel, 2005). In the mechanistic theory there is no accounting for the energy dissipation (entropy production) accompanying the transport process. The terms entropy and entropy production do not occur in the mechanistic theory. Therefore, the symmetry of the matrix of transport coefficients is not guaranteed. For the most important coupled transport processes in soils, water and heat transport, the so-called Philip and De Vries theory (Philip and de Vries, 1957), the relation between the two coupling coefficients is not discussed.

Modern development and outlook

The branch of science called “Non-equilibrium Thermodynamics” is now split into two sub-branches. The first one, dealt with above, is now called “Linear Non-equilibrium Thermodynamics.” Indeed, all transport equations presented above are linear.

This sub-branch of science deals with processes that are “not far from equilibrium.”

The second sub-branch is now called “Non-linear Non-equilibrium Thermodynamics” (Glansdorff and Prigogine, 1971).

Its great proponent was Ilya Prigogine, who received the Nobel Prize for Chemistry for his work in 1977. This sub-branch of science deals with “violent” processes (“far away from equilibrium”), such as Liesegang rings and atom bombs. The natural transport processes in the soil are never “violent”, and, as long as Darcy’s law (one of the primary energy dissipating processes) holds, all coupling processes fall in the park of “not far from equilibrium.” However, if there are cases where Darcy’s law breaks down and turns into the non-linear Forchheimer equation (that is when the water in the soil becomes turbulent), soil physicists may have to turn their attention to this latest branch of thermodynamics.

Addendum

Pieter Hendrik Groenevelt: August 8, 1937–February 10, 2023. [Groenevelt and Bolt \(1969, 1972\)](#) (Photograph provided by Cameron Grant).

The unexpected death of Pieter happened when he was in the middle of polishing this chapter. The editorial team felt it would be appropriate to pay tribute to him as part of what turned out to be his last solo paper.

Pieter was born on the island of Java in what was then the Dutch East Indies, to where his father – an agricultural engineering consultant – and mother had emigrated from the Netherlands. Following the Japanese invasion of the island early in 1942, Europeans were interned, with Pieter, his mother and three sisters being locked up in what Pieter described as a series of concentration camps. His father, who was captured after the fall of Java, was shipped to the island of Kyushu, Japan as a prisoner-of-war. There he died from pneumonia less than 2 years later as a result of working in the horrendous conditions in a coal mine. Pieter was dying from starvation and tropical diseases when the war ended but managed to survive until the gates of the camp were opened and the internees got access to the abundant food outside. Pieter wrote that his experiences at that period in his life were as bad as it gets and he would be able to deal with whatever was thrown at him later.

His mother returned to the Netherlands with Pieter and his sisters in 1946. Pieter worked hard to catch up with his missed schooling and eventually gained a place at the University of Wageningen, gaining a Bachelor of Science in Tropical Land and Water Management, followed by a Master of Science in Irrigation and Drainage. He then went on to study for a doctorate in Soil Physics guided by G. ‘Gerry’ H. Bolt focused on non-equilibrium thermodynamics. Pieter’s thesis, entitled ‘Coupling phenomena in soil transport processes’ resulted in a 30-page review article on non-equilibrium thermodynamics related to the soil-water system (Groenevelt and Bolt, 1969). After a brief period working on the measurement of soil density and water content by gamma-ray attenuation, Pieter was awarded a CSIRO Postdoctoral Fellowship to work in the CSIRO Division of Environmental Mechanics, Canberra, Australia. His tenure of that position was abruptly and acrimoniously curtailed following a disagreement with the Director, John Philip, forcing Pieter, his wife and children to seek a new position at very short notice. Happily, this was solved by an invitation to join the Department of Land Resource Science at the University of Guelph, Canada, which remained his academic home.

The move provided new environments for Pieter to think about, starting with the arctic which piqued his interest in the functioning of freezing and frozen soils. He produced a series of papers dealing with transport of heat and water in frozen and unfrozen soils, tackling the issues of water potential and structural changes resulting from freezing and thawing. Pieter continued to work on thermodynamics but he also developed his analytical skills, which he applied to practical problems, particularly those associated with soil management. He considered the effects of tillage and cropping systems on soil stability and structure,

particularly in relation to soil erosion. The application of liquids, such as those from landfills, either in circulating systems or spray irrigation, was considered both from the viewpoint of the breakdown of surface structure but also from the changes in contact angle between the liquid and the soil fabric. The latter aspect was also investigated with respect to liquid manure and the impact on evaporation from soil. The different approaches adopted to evaluate the effects on soil conditions following the various waste materials caused Pieter to develop new ways of assessing changes.

New approaches were developed for using time domain reflectometry to measure bulk soil electrical conductivity (σ) and the dielectric constant. To correct for influences of the measuring system on σ , reflection measurements were compared with a reference measurement performed in air. To avoid using empirical equations to deal with the effects of changing water content on electrical conductivity, the theory of dispersive behavior was used to develop theoretical model.

To measure the saturated hydraulic conductivity and of slowly permeable clay liners, using single-ring or well permeameters (e.g., Guelph permeameter), Pieter and his colleagues produced an analytical solution describing the transient, capillary-dominated, early-time estimate of these flow parameters. Here, an analytical solution was utilized for early-time, one-dimensional infiltration at an initial constant head followed by a falling-head phase.

Pieter's childhood experiences resulted in him being incredibly supportive of students. He was a very patient and kind mentor but was also able to encourage them to achieve more than they thought themselves capable. There was always a strong element of freedom and fun in his approach but it was always backed up by enthusiasm and inexhaustible hard work. As a colleague he was also there to help if asked. He was fiercely analytical but his criticisms were always balanced.

Abstract

Immiscible fluids are ubiquitous in the subsurface, occurring naturally (air and water in the vadose zone) or because of human activity [non-aqueous phase liquids (NAPLs)]. The chapter gives an overview of the dominant physical and chemical processes that govern the fate and transport of air, water, NAPL, and NAPL components, in soil. The vertical distribution of air, water, and NAPL at equilibrium is explained. Laboratory measurements of relative permeabilities of water-wet sandstones from two studies are presented, and salient features identified. The simplest models used to describe the mass transfer of NAPL components in soil between aqueous, gaseous, and solid phases are described.

Key points

- Immiscible fluids are ubiquitous in the subsurface, occurring naturally or because of human activity.
- Field-scale simulators use empirical relationships between relative permeability and capillary pressure and phase saturations, which result from complex processes and are therefore difficult to estimate accurately.
- Even for the simplest air-water-NAPL fluid combinations at equilibrium, the relative permeability to NAPL depends on the saturation of all three fluids *and* their history.
- A number of empirical models for three-fluid phase relative permeability have been proposed, but their applicability is poorly understood.
- Mass transfer of NAPL components within strongly water-wet soil involves three main processes: (a) *volatilization*, (b) *dissolution*, and (c) *sorption*.
- Emerging areas of research include new closure equations based on detailed information of pore structure extracted from X-ray micro-computed tomography data.

Nomenclature

Roman letters

a_{wo} (m^{-1})	specific interfacial area between the aqueous phase and NAPL mixture per unit bulk volume
C_s^β ($kg\ kg^{-1}$)	mass of the sorbed NAPL component β per unit dry mass of soil
C_v^β ($mol\ m^{-3}$)	mass of dissolved NAPL component β per unit volume of the aqueous phase
C_{w*}^β ($mol\ m^{-3}$)	aqueous solubility of pure component β
C_g^β ($mol\ m^{-3}$)	concentration of NAPL component β in the gas phase
$D(\Theta_w)$ ($m^2\ s^{-1}$)	soil water diffusivity

f_{oc} (kg kg ⁻¹)	fraction of organic carbon of soils
g (m s ⁻²)	gravitational acceleration
h (m)	matric head
H (m)	height of NAPL column (cf. Fig. 5)
$J(S_w)$ (.)	Leverett J-function
k (m ²)	intrinsic permeability
k_α (m ²)	effective permeability to phase α
$k_{r\alpha}$ (.)	relative permeability to phase α ($= k_\alpha/k$)
k_{wo}^β (m s ⁻¹)	mass transfer coefficient between the aqueous phase and NAPL mixture
$K(\Theta_w)$ (m s ⁻¹)	hydraulic conductivity
K_d^β (m ³ kg ⁻¹)	soil/water partitioning or soil/water distribution coefficient of NAPL component β
K_{oc}^β (m ³ kg ⁻¹)	organic carbon partitioning coefficient
K_H^β (Pa m ³ mol ⁻¹)	Henry's Law constant
p^β (Pa)	partial pressure of NAPL component
p_*^β (Pa)	equilibrium vapor pressure of pure component β
Δp (Pa)	difference in pressures of two fluids across the interface
p_c (Pa)	capillary pressure ($= p_n - p_w$)
p_n (Pa)	pressure of the non-aqueous phase
p_w (Pa)	pressure of the aqueous phase
P_n (Pa)	macroscopic pressure in the non-wetting phase
P_w (Pa)	macroscopic pressure in the wetting phase
P_α (Pa)	macroscopic pressure of fluid α
P_{wn} (Pa)	macroscopic capillary pressure
P_{ow} (Pa)	NAPL-water macroscopic capillary pressure
P_{aw} (Pa)	air-water macroscopic capillary pressure
P_{ao} (Pa)	air-NAPL macroscopic capillary pressure
q_α (m s ⁻¹)	volumetric flow rate of fluid α per unit bulk cross-sectional area
r (m)	pore radius
R (J K ⁻¹ mol ⁻¹)	universal gas constant ($= 8.314$ J K ⁻¹ mol ⁻¹)
R_1, R_2 (m)	principal radii of curvature of the interface
S_α (.)	saturation of fluid phase α
S_{gr} (.)	residual gas saturation
S_{wi} (.)	irreducible water saturation
V_α (m ³)	volume of fluid α within REV
V_v (m ³)	volume of void space within REV
V_t (m ³)	bulk volume of REV
z (m)	vertical coordinate
z_c (m)	critical height

Greek letters

θ (rad)	contact angle
θ_{aw} (rad)	air-water contact angle
θ_{ow} (rad)	NAPL-water contact angle
Θ_w (.)	water content ($= \phi S_w$)
μ_α (Pa s)	dynamic viscosity of fluid α
ξ (.)	parameter defining NAPL (oil) extent in vertical equilibrium profile
ρ_α (kg m ⁻³)	density of fluid α
σ (N m ⁻¹)	interfacial tension
σ_{ow} (N m ⁻¹)	equilibrium NAPL-water interfacial tension
σ_{aw} (N m ⁻¹)	equilibrium air-water interfacial tension
σ_{ao} (N m ⁻¹)	equilibrium air-NAPL interfacial tension
ϕ (.)	porosity
χ_o^β (.)	mole fraction of NAPL component β in the NAPL

Subscripts and superscripts

i	initial (non-equilibrium)
o	NAPL (oil) phase
w	aqueous phase
a	air phase
g	gaseous (air) phase
n	non-wetting phase
r	relative (permeability) or residual (saturation)
α	fluid phase; $\alpha = (w, a, g, o)$ denote water, air, gas, oil, respectively
β	NAPL component

Abbreviations

REV (m^3)	representative elementary volume
NAPL	non-aqueous phase liquid
μCT	micro-computed tomography

Introduction

Soils are located near the surfaces of land on Earth. As such, they contain variable amounts of air and water, which are immiscible, i.e., they cannot mix to form a single phase in all ratios. Soils are also subject to contamination by human activities. Many of the contaminants commonly found in soils are liquids that are immiscible with air and water. These immiscible contaminants are principally fuel hydrocarbons (petroleum liquids) and industrial solvents, and are referred to as non-aqueous phase liquids (NAPLs). Fuel hydrocarbons tend to be NAPLs that are less dense than water, or *light* NAPLs (LNAPLs). Industrial solvents, especially chlorinated hydrocarbons, tend to be denser than water, or *dense* NAPLs (DNAPLs). Examples of common NAPLs are listed in Table 1.

The increased interest in better understanding NAPL behavior in soils is largely driven by our concern for water quality. As water moves downward through soils, dissolved NAPL components can migrate to potable water supplies. Furthermore, volatile components of NAPLs may partition to the air occupying the pores of the soil and move through the soil. These volatilized components can subsequently partition into pore water and enter potable water supplies. The migration of NAPL components and, ultimately, their contamination of groundwater are affected by the distribution of NAPL in soils.

The behavior of water, air, and NAPL in soils can be explored using simulation models. These simulators solve fundamental equations governing the movement of fluid phases to predict their movement over a selected area of interest, i.e., the simulation domain. To produce reliable predictions, models need to be given the soil characteristics, the initial distribution of relevant fluid phases across the simulation domain, and relevant multiphase flow properties, e.g., relative permeability to the three fluids. Fig. 1 presents a sample of a simulation model output. It shows the consequences of a spillage of two NAPLs on the soil surface, a LNAPL (top row) and a DNAPL (bottom row) (Kikumoto and Nakamura, 2017). During the initial stages (the left two columns) both NAPLs follow a similar pattern—they move downwards until they reach a layer of low permeability. The low permeability zone acts as a barrier, causing them to change their main direction of flow to horizontal and to spread over its surface until they can move downwards again toward the next barrier, where the movement becomes horizontal again. The differences between the migration of the LNAPL and the DNAPL are subtle. The former moves somewhat slower: in the second column its front has just reached the bottom of the lower barrier, whereas the DNAPL front has moved well below it. As the migration continues, the difference between the LNAPL and the DNAPL becomes more and more apparent, with the former moving slower and creating a mound above the groundwater table (blue line) and the latter penetrating the groundwater. Beyond the time instances shown in the figure this distinctly different behavior of LNAPL and DNAPL would continue, with the former moving along the groundwater surface and the latter along the impermeable aquifer bottom. Simulations of this kind offer valuable insights into behavior of fluids in soils at field (m- to km-) scales. However, at present, the reliability of these simulations is strongly restricted by the uncertainty in some of the input parameters, most notably the permeability and relative permeability and their distribution in space.

The movement of air, water, and NAPLs in soils is driven by differences in density between the fluids (i.e., gravity), differences in fluid pressures between the fluid phases, and the gradient of pressure within each fluid phase. Pressure distribution within all fluid phases depends on the size and shape of the pores containing the fluids and the configuration of fluids inside these pores, which may even depend on whether the volume occupied by a particular fluid phase is increasing or decreasing in the soil. Once the net forces acting on the fluids become zero, the system has reached a mechanical equilibrium and the movement stops. The corresponding distribution of fluids depends on all parameters affecting fluid motion, including the displacement history.

Table 1 Density, viscosity, aqueous solubility, and interfacial tension of selected NAPLs at selected temperatures.

Fluid distribution in the pore spaces at equilibrium

At equilibrium the distribution of air, water, and NAPL in soil is dictated by their pressures and the molecular forces of attraction to each other and to the surfaces of the soil grains. 'Wettability' describes the propensity of a fluid to maintain contact with a solid surface in the presence of a second fluid, which in turn depends on a number of physical and chemical properties of the fluids and the solid. One measure of wettability is the contact angle, θ , that the fluid makes with the solid surface: the smaller the θ , the greater its wettability. A 'wetting fluid' ($\theta < 90^\circ$), will spread over the solid surface and a 'nonwetting fluid' ($\theta > 90^\circ$) tends to avoid contact with the solid. The wettability of a fluid determines whether it will occupy larger or smaller pores in the soil, and whether it breaks up into isolated clusters ('capillary trapped') or forms wetting layers along the grain surface at low saturations.

In soils, air is the nonwetting fluid, and water is generally the wetting fluid. Therefore, water typically occupies the smallest pore spaces in soils and air occupies the largest pore spaces. It is generally accepted that NAPLs, if present, spread over water surfaces and form a layer between the water and air. NAPLs occupy pore spaces intermediate to those occupied by water and air. However, there are several exceptions to these conditions. One exception occurs under mixed wettability, in which there is pore-scale and sub-pore scale heterogeneity in the hydrophilicity of the grain surface. Mixed wettability may arise if organic compounds render hydrophobic the surface of grains in direct contact with NAPLs, resulting in NAPLs wetting parts of the grains instead of water. Another exception is where the NAPL has a complex structure in which one end of the compound is hydrophilic and the opposite end is hydrophobic.

Fig. 1 Migration of a LNAPL (top row) and a DNAPL (bottom row) in an idealized soil profile containing regions of low permeability (grey rectangles) located above the water table (blue horizontal lines). NAPL concentration is shown as a shade of grey. Vertical columns correspond to four instances after the start of spillage, with time increasing from left to right. Reproduced with permission and modified from Kikumoto M and Nakamura K (2017) Simulation of seepage flow of non-aqueous phase liquid in vadose zone. *Environmental Geotechnics* 4(3): 171–183. doi: 10.1680/jenge.15.00011.

Contact angle is a function of not only the interfacial energy of each fluid with the solid surface but also the interfacial tension between the fluid pairs. Interfacial tension is the net force of attraction between molecules at the interface of two immiscible fluids per unit length. It can also be defined as energy per unit interfacial area required to increase that area by one unit. In soils, the distribution of immiscible fluids is different for identical pore geometries and fluid pressures if the interfacial tensions are different. Further details about interfacial tension, including tabulated values for selected liquids and their vapor, can be found in the *Capillarity* chapter.

A basic equation of capillarity is the Young-Laplace equation, which considers a single interface separating two immiscible fluids at mechanical equilibrium, such as water and air in a single pore. It relates the difference in fluid pressures across the interface to the interfacial tension and the curvature of the interface at mechanical equilibrium. The Young-Laplace equation is:

$$\Delta p = \sigma \left(\frac{1}{R_1} + \frac{1}{R_2} \right) \quad (1)$$

in which Δp is the difference in pressures of the fluids across the interface, σ is the interfacial tension between the fluid pair, and R_1 and R_2 are the principal radii of curvature of the interface in orthogonal directions. Δp is closely related to the *capillary pressure*, which is conventionally defined in petroleum engineering and in soil physics as:

$$p_c = p_n - p_w \quad (2)$$

where p_n and p_w are the pressures of the non-aqueous phase and the aqueous phase, respectively. The interface separating the nonwetting and wetting fluids is curved convex toward the nonwetting fluid, which means that the pressure of the nonwetting fluid is greater than the wetting fluid. Consequently, the capillary pressure is always positive using the definition given by Eq. (2). In a cylindrical pore the radii of curvature of the fluid-fluid interface in Eq. (1) are equal ($R_1 = R_2 = R$), i.e., the interface has a shape of a sphere. From the geometry of the interface and the pore, the interface radius can be converted to the pore radius, r , by $\cos\theta = r/R$. Eq. (1) then reduces to:

$$\Delta p = \frac{2\sigma \cos\theta}{r}. \quad (3)$$

The pores within the soils have complex geometry and fluid phases within them create numerous interfaces. Fig. 2 shows the distribution of air in a packed column of spherical particles initially saturated with water, then allowed to drain by gravity, and finally imbibed with water again (Tanino et al., 2020). Each air cluster has multiple interfaces, some of them with the solid and some with water. However, for predicting behavior of fluids at the field scale or even the Darcy scale it is impractical—and often unnecessary—to simulate the distribution of fluid phases at such level of detail. Spatial averaging is therefore applied to all relevant properties and fundamental laws to switch from the scale of individual pores to Darcy scale, which is referred to in this chapter as the macroscopic scale. Averaging is performed over a representative elementary volume (REV) which is sufficiently large to yield statistically representative average properties but sufficiently small to exclude macroscopic heterogeneity (Bear, 1960).

Fig. 2 A cross-section of a 38 mm-long, 21 mm-diameter packed column of glass spheres after secondary imbibition visualized by X-ray micro-computed tomography (μ CT). Each pixel in the tomogram (A) was labelled as being occupied by the solid (brown), water (blue), or air (red) to generate the segmented image (B). Configurations of the solid, water, and air are shown in (C), (D), and (E), respectively. Raw image from Tanino Y, Ibekwe A and Pokrajac D (2020) Impact of grain roughness on residual nonwetting phase cluster size distribution in packed columns of uniform spheres. *Physical Review E* **102**(1): 013109. doi: 10.1103/PhysRevE.102.013109 (A); Post-processing and segmentation by Hamza H (2021) *Impact of Grain Roughness on Capillary Trapping in Porous Media*. MSc thesis, University of Aberdeen: United Kingdom. (B–E).

The size of REV can be based on various quantities such as porosity and saturation. Porosity can be expressed as:

$$\phi = \frac{V_v}{V_t} \quad (4)$$

where V_v is the volume of the voids within the REV and V_t is the bulk volume of the REV which includes both voids and the solid phase. In Fig. 2B, an air-water-solid system, V_v is the total volume occupied by water (blue) and air (red), and V_t contains also solid phase (brown). The fractional volume of the void space occupied by fluid phase α , is termed *saturation*, and is defined as:

$$S_\alpha = \frac{V_\alpha}{V_v} = \frac{V_\alpha}{\phi V_t} \quad (5)$$

where $\alpha = (w, a, o)$ for water, air, and NAPL, respectively, and V_α is the volume of the fluid phase α within the REV. The sum of the saturations of all fluid phases occupying the pores within a REV is equal to unity.

Fig. 3 illustrates the process of establishing the size of the REV for porosity and the residual air saturation. It shows how both porosity and the air saturation vary with the size of the volume from which they have been determined until a certain point when they become stable. This point defines the lower limit of the REV, i.e., the minimum size of the averaging volume which can produce physically meaningful results. It can also be noticed that the minimum REV for porosity and air saturation are different. This means that the REV for porosity should not be extrapolated to other quantities. In practical terms the REV determines the size of a laboratory sample which is sufficiently large to produce physically meaningful results.

Fig. 3 Distribution of porosity and residual air saturation after secondary imbibition in the same packed column of glass spheres as that in Fig. 2. (A) Vertical distribution of S_{gr} and ϕ averaged over 4.9 mm-diameter $\times$ 5.0 μm -thick tomograms. (B) 3D rendering of the residual air in the middle of the packed column; water and grains are not shown. (C) S_{gr} (red) and ϕ (blue) averaged over cylindrical volumes of constant (4.9 mm-diameter) cross-section and increasing number of tomograms, at 50 μm intervals, in the direction of increasing z . Arrows in (C) depict REV for ϕ (blue) and S_{gr} (red) and are intended as a guide to the eye only. Data in (A, C) from Pentury JG (2021) *Impact of Grain Roughness on Capillary Trapping in Porous Media*. MSc Thesis, University of Aberdeen: United Kingdom. (B) Modified from Tanino Y, Ibekwe A and Pokrajac D (2020) Impact of grain roughness on residual nonwetting phase cluster size distribution in packed columns of uniform spheres. *Physical Review E* **102**(1): 013109. doi: 10.1103/PhysRevE.102.013109.

Upscaling from a single pore to the REV needs to be done for all relevant quantities, including capillary pressure. Macroscopic capillary pressure is usually defined as:

$$P_{wn} = P_n - P_w \quad (6)$$

where P_n , P_w are the *macroscopic* pressures in the non-wetting and wetting fluid, respectively. P_n , P_w are average pressures over the entire fluid volume within the REV. It is possible to derive an alternative definition by rigorous averaging of capillary pressure across individual interfaces within the REV (Starnoni and Pokrajac, 2020), but this definition is yet to be applied to practical simulation models. It should be noted that the two definitions do not in general yield identical values even when the fluid phases are at equilibrium.

Fluid content in soil is largely determined by the macroscopic capillary pressure. For a two-phase system the relationship $P_{wn}(S_w)$ can be expressed by using

$$J(S_w) = P_{wn} \frac{\sqrt{k/\phi}}{\sigma \cos \theta} \quad (7)$$

where $J(S_w)$ is the Leverett J-function, commonly used to scale the results of $P_{wn}(S_w)$ measurements, and k is intrinsic (single phase, liquid) permeability. The RHS of Eq. (7) is very similar to a re-arranged version of Eq. (3) in which the pore radius is replaced with an estimate of the representative radius of pores based on permeability and porosity.

Several models have been proposed to describe the relationship between capillary pressure and fluid saturations mathematically. The most common models for describing S_{α} - P_{α} relations have originally been proposed for two-phase (air-water) soil systems. Brooks and Corey (1964) model provides a relationship between the air-water capillary pressure, P_{aw} , and the dimensionless effective saturation with water:

$$\hat{S}_w = \frac{S_w - S_{wi}}{1 - S_{wi}} \quad (8)$$

where S_{wi} is the irreducible (i.e., irreducible by gravity or realistic pressure gradients) water saturation. The relationship contains two parameters: the so-called air capillary entry pressure and a fitting parameter related to the pore-size distribution. van Genuchten (1980) model relates S_w to P_{aw} , and has two fitting parameters; widely used empirical models for S_{α} - P_{α} are presented in the *Water Retention and Characteristic Curve* chapter.

Extension to air-NAPL-water-soil systems

In air-NAPL-water systems in soils, water is usually the most wetting fluid, air is the non-wetting fluid, and the NAPL has intermediate wettability. The spatial distribution of the three fluid phases depends on the relative magnitudes of their respective interfacial tensions. When a drop of LNAPL is dispensed onto a flat water surface in contact with air, it may behave in the following ways (Hirasaki, 1993):

- If $\sigma_{aw}^i < \sigma_{ow}^i + \sigma_{ao}^i$, where superscript i denotes the initial values of the interfacial tensions between the phases, three phases will meet at a point and the drop will remain stationary.
- If $\sigma_{aw}^i > \sigma_{ow}^i + \sigma_{ao}^i$ (Fig. 4A) it is not possible to balance the three interfacial tensions and NAPL spreads as a film. The film thickness depends on the relative strength of the interfacial tensions at equilibrium. If equilibrium air-water interfacial tension,

Fig. 4 Three fluids in contact. If $\sigma_{aw}^i > \sigma_{ow}^i + \sigma_{ao}^i$ (A) the NAPL will spread between the air and water and form a thin film. The system will be in equilibrium with a NAPL lens if equilibrium air-water interfacial tension is smaller than the sum of the other two (B). Similar spreading phenomena occur in porous media, where NAPL layers often separate water and air in the corners of pores (C). Based on Figs. 1 and 2 in Zhou D and Blunt MJ (1997) Effect of spreading coefficient on the distribution of light non-aqueous phase liquid in the subsurface. *Journal of Contaminant Hydrology* 25: 1–19. doi: 10.1016/S0169-7722(96)00025-3.

σ_{aw} , is smaller than the sum of the other two interfacial tensions, the resulting film is very thin and in equilibrium with the remaining NAPL (Fig. 4B). In contrast, if σ_{aw} still dominates, the NAPL film may swell infinitely. The latter case is referred to as a spreading system. Note that $\sigma \leq \sigma^i$ for any pair of phases.

The same spreading phenomena can occur in the pore space of soil. Water, as most wetting fluid phase, occupies the narrowest portions of the pore space and the corners of larger pore bodies; air is non-wetting and hence occupies the middle region of the larger pores; NAPL may form a layer between them (Fig. 4C). For such a configuration, NAPL and water combined may be treated as a single, pseudo-wetting phase, i.e., the air-NAPL capillary pressure can be represented as a function of total liquid saturation $S_w + S_o$, as first suggested by Leverett (1941) and subsequently confirmed by Parker et al. (1987). This approximation is only valid for a spreading system.

Zhou and Blunt (1997) use the above approximation and Leverett J-function to express capillary pressures in a water-wet air-NAPL-water system that may be established in soil by gravity drainage. Fig. 5A is a sketch of the vertical arrangement of the three fluid phases in a soil, in the vicinity of the groundwater table: starting from the deeper layers of soil where it is fully saturated with water, $z = 0$ is the level at which NAPL is first mobile, or connected, and $z = H$ is the height at which air is first continuous. This means that below $z = 0$ the only fluid present is water, between $z = 0$ and $z = H$ two fluids—water and NAPL—are present, and above $z = H$ all three fluids are present. The maximum elevation for the region that contains NAPL is determined by the following parameter:

$$\xi = \frac{\sigma_{ow} \cos \theta_{ow} (\rho_o - \rho_a)}{\sigma_{ao} \cos \theta_{ao} (\rho_w - \rho_o)} \quad (9)$$

If $\xi \leq 1$ oil spreads across the entire soil column. However most fluid systems have $\xi > 1$, with oil saturation reducing to zero at a level z_c given by

$$z_c = \frac{\xi H}{\xi - 1} \quad (10)$$

Fig. 5 Vertical equilibrium in a soil with $\xi > 1$ (Eq. 9) close to the water table. Typical arrangement of air, water, and NAPL (A) and their relative volumes (B) as a function of depth. Modified from Zhou D and Blunt MJ (1997) Effect of spreading coefficient on the distribution of light non-aqueous phase liquid in the subsurface. *Journal of Contaminant Hydrology* 25: 1–19. doi: 10.1016/S0169-7722(96)00025-3.

The expressions for oil-water, air-oil, and air-water capillary pressures are, respectively:

$$\begin{aligned} P_{ow} &= (\rho_w - \rho_o) g z = \sqrt{\frac{\phi}{k}} \sigma_{ow} \cos \theta_{ow} J(S_w), 0 \leq z \leq z_c \\ P_{ao} &= (\rho_o - \rho_a) g (z - H) = \sqrt{\frac{\phi}{k}} \sigma_{ao} \cos \theta_{ao} J(S_w + S_o), \quad H \leq z \\ P_{aw} &= (\rho_w - \rho_a) g z - (\rho_o - \rho_a) g H = \sqrt{\frac{\phi}{k}} \sigma_{aw} \cos \theta_{aw} J(S_w), \quad z_c \leq z \end{aligned} \quad (11)$$

The first equality sign follows from the hydrostatic pressure distribution in water, NAPL, and air. The second equality sign relates capillary pressures to fluid saturations using the Leverett J-function (see Eq. 7). For known $J(S_w)$, solving above equations for S_w , S_o , S_a yields the distribution of the three fluids as functions of the level above the water-oil interface ($z = 0$). The typical shape of these distributions is shown in Fig. 5B.

Based on the above equations, Zhou and Blunt (1997) have also developed a method for using measurements of $S_w(z)$ in an air-water system in capillary-gravity equilibrium to predict the distribution of NAPL, water, and air in a three-phase experiment. They assumed a strongly water-wet system with $\cos \theta_{aw} = \cos \theta_{ow} = 1$. The measured and predicted three-phase distributions are in good agreement, confirming that the approximate model of the three-phase behavior was able to capture its main features in the analyzed strongly water-wet gravity-drained systems.

Another, more general extension of the two-phase S_α - P_α relations to air-NAPL-water systems was proposed by Parker et al. (1987). It involves using a scaling parameter to multiply the capillary pressure between each pair of fluid phases and relating these scaled capillary pressures to the corresponding effective liquid saturations. The authors have shown that it is possible to find a set of scaling parameters such that relationship between the scaled pressures and the corresponding liquid saturations is universal, i.e., it is identical for all possible pairs of fluids in both two-phase and three-phase systems. The scaling factors can be determined from S_α - P_α data in two-phase or three-phase systems or predicted from ratios of interfacial tensions.

The relationship between fluid content and capillary pressure is very complex and often not unique, i.e., it depends on the history of fluid movements which causes hysteresis in S_α - P_α relationship. There are three major reasons for hysteresis:

- *Fluid entrapment.* When displaced by a more wetting fluid, the nonwetting fluid can become trapped and isolated in the soil pores. This happens only when wetting fluid is displacing the non-wetting fluid, and causes the wetting fluid to occupy larger pores on imbibition saturation paths than it would on drainage saturation paths for the same wetting-fluid saturation. In larger pores the radii of curvature of the interfaces will also be larger (see Eq. 3), which means the capillary pressure will be smaller (see Eq. 1).
- *Pore-geometry effects,* which include the so-called ‘ink-bottle effect’: an imbibing wetting fluid will stop in larger pores whereas a draining wetting fluid will stop at the narrower pores.
- *Contact angle changes with direction of fluid movement* (draining versus imbibing). Advancing and retreating contact angles for the same fluid are usually different. A different contact angle for the same fluid content will yield a different capillary pressure. However, the change in contact angles in soils with direction of fluid movement is very complex, because the grain surfaces of soil are irregular at the microscopic scale.

Further details and a discussion of hysteresis can be found in the chapter *Hysteresis*.

In air-water systems, there are only two possible combinations of fluid movement: water is either imbibing (and displacing air out of a sample) or draining (letting air in). In air-NAPL-water systems, there are six possible combinations of fluid movement, which makes predicting, or modelling, three-fluid S_α - P_α behaviour more difficult. Despite difficulties it is possible to model hysteretic air-NAPL-water S_α - P_α relations in which water is the wetting fluid. Parker and Lenhard (1987) have proposed a model which accounts for fluid entrapment by using apparent saturations and phase saturation-path history. The authors have shown that the model can successfully reproduce several cycles of imbibition and drainage in an air-NAPL-water system.

Movement of immiscible fluids in soils

The description of the movement of a fluid in unsaturated soils is based on a modification of Darcy’s law for saturated water flow, which was developed in 1856. In 1907, Buckingham modified Darcy’s law to describe unsaturated water flow by replacing the saturated hydraulic conductivity with an unsaturated hydraulic conductivity that is a function of water content or capillary pressure. Over the years, the modification made by Buckingham and the recognition that the hydraulic conductivity consists of fluid-dependent and -independent elements has yielded what is commonly referred to as a generalized form of Darcy’s law:

$$\mathbf{q}_\alpha = -\frac{k_\alpha(S_\alpha)}{\mu_\alpha} (\nabla P_\alpha - \rho_\alpha \mathbf{g}) \quad (12)$$

for phase α , in which $\mathbf{q}_\alpha$ is the volumetric flow rate of α per unit bulk cross-sectional area of the porous medium (also known as the Darcy velocity), $k_\alpha(S_\alpha)$ is the permeability of that medium to α at a particular saturation S_α , μ_α is the viscosity of α , P_α is the pressure

of α , ρ_α is the density of α , and g is the gravitational acceleration. The first term in brackets in Eq. (12) is the gradient of pressure, $\nabla P_\alpha = \partial P_\alpha / \partial x_i$, and x_i , $i = 1, 2, 3$ is a symbol representing the Cartesian coordinates x , y , and z .

Darcy's law is combined with the mass balance equation for fluid α , which can be expressed as:

$$-\nabla \rho_\alpha q_\alpha = \frac{\partial \rho_\alpha \phi S_\alpha}{\partial t} \quad (13)$$

yielding the flow equation

$$\nabla \left[\frac{\rho_\alpha k_\alpha(S_\alpha)}{\mu_\alpha} (\nabla P_\alpha - \rho_\alpha g) \right] = \frac{\partial \rho_\alpha \phi S_\alpha}{\partial t}. \quad (14)$$

A flow equation can be written for each fluid phase α present in soil. The sum of the saturations of all these phases is equal to unity.

In unsaturated soil, it is commonly assumed that air in the soil is not moving and is at atmospheric pressure so that only the flow equation for water is required, and it is more practical to use water content, $\Theta_w = \phi S_w$, instead of saturation. Water is assumed incompressible ($\rho_w = \text{const}$), and its pressure is expressed via the matric head, h , defined as:

$$h = \frac{P_w}{\rho_w g} \quad (15)$$

Expressing Eq. (14) in terms of the matric head, and assuming that water is moving only in the vertical direction yields Richard's equation:

$$\frac{\partial}{\partial z} \left[K(\Theta_w) \left(\frac{\partial h}{\partial z} + 1 \right) \right] = \frac{\partial \Theta_w}{\partial t} \quad (16)$$

where z is the vertical coordinate pointing upwards and $K(\Theta_w) = \rho_w g k_w / \mu_w$ is the hydraulic conductivity. The unity in the brackets expresses the effect of gravity. If water is also moving in a horizontal direction an analogous equation applies, but without the unity.

Overview of multiphase numerical models used for field-scale simulations

Simulation of multiphase flow in soils is based on the flow equations applied to field-scale problems. The process starts with defining a conceptual model, i.e., the description of the domain of interest and the relevant processes. This governs the selection of the flow equations, which are solved numerically using a computer code. The input data usually required for simulation of multiphase flow include soil and fluid characteristics such as ϕ , ρ_α , $k_\alpha(S_\alpha)$, and $P_c(S_\alpha)$, the initial distribution of the fluid phases α across the simulation domain, boundary conditions, and computational parameters such as spatial and temporal steps. Based on these inputs the code calculates how the distribution of pressure and saturation of each fluid phase across the simulation domain changes in time. If physically possible, after sufficiently long simulation time all fluid phases will stop moving because equilibrium pressure and saturation distributions have been reached.

The general procedure described above can be applied to solve the Richards equation for either water content or pressure. In the former case the known model input includes water density and viscosity and the following relationships: $K(\Theta_w)$ and the soil water diffusivity $D(\Theta_w) = K(\Theta_w) dh/d\Theta_w$. These relationships can be expressed using the empirical formulas such as [van Genuchten \(1980\)](#) or [Brooks and Corey \(1964\)](#) models, or even as look-up tables based on experimental results. Starting from the initial distribution of water within the soil column, simulation produces a series of water distributions at different times. The corresponding water pressure can be tracked via $D(\Theta_w)$.

To simulate movement of both water and air, and possibly an additional fluid such as NAPL, the simulation model needs to solve either two-(fluid) phase or three-phase flow equations. In the former case there is a flow Eq. (14) for each phase, and another equation stating that the sum of fluid saturations equals unity. These are combined with an equation that relates capillary pressure to the pressures in the two phases (Eq. 6). The input data include density, viscosity, and $k_\alpha(S_\alpha)$ for each phase, and the relationship between P_c and saturation of one of the phases. The simulation software calculates the distribution of both pressure and saturation for each phase as they evolve in time.

The process for three-phase simulations is analogous, with input data including density, viscosity, and $k_\alpha(S_\alpha)$ for each phase, and relationships between capillary pressure and a saturation for each combination of two phases. Results show the evolution of saturation and pressure distribution for each phase.

The accuracy of simulation models crucially depends on the accuracy of all input data, some of which are very difficult to estimate. The remaining part of this section is focused on the key parameter which determines the motion and ultimately the distribution of fluids in a soil—relative permeability, $k_{r\alpha} (= k_\alpha/k)$. For this reason, the accuracy of relative permeability is critical for obtaining good multiphase flow simulation results.

Relative permeability

Where the pore space of a porous medium is occupied by more than one fluid phase, the permeability of that medium to one phase is affected by the presence of the other phases, and $k_\alpha = k_\alpha(S_\alpha)$. Because the cross-sectional area available to each phase is restricted

by the presence of the other phases, it is widely assumed in numerical simulators that $k_{rx} \leq 1$. However, laboratory experiments in water-NAPL-rock systems show that the permeability to NAPL is enhanced by the presence of water such that $k_{ro} > 1$ if S_o is sufficiently high and the water is stationary (Berg et al., 2008 and references therein). More recently, Christensen and Tanino (2017) showed that this enhanced permeability occurs not only in water-wet rock but in mixed-wet rock also.

Even in two-fluid systems relative permeability is notoriously difficult to measure under capillary-dominated conditions representative of the subsurface. $k_x(S_x)$ for a given system is a function not only of S_x but also saturation history and wettability. In mixed-wet media such as NAPL-contaminated soils and oil reservoir rock, capillary end effects demand the use of Darcy-scale simulators to interpret displacement experiments and to obtain $k_x(S_x)$ and residual NAPL or gas saturation (e.g., Tanino and Christensen, 2019). Where three fluids are present in the pore space, $k_x(S_x)$ is a function not only of its own saturation but that of the other two fluids. Furthermore, saturation history now comprises the co-evolution of three parameters (S_x for $\alpha = o, w, g$) which is not necessarily monotonic.

Because of the above challenges, three-phase relative permeabilities are rarely measured in petroleum engineering or in soil sciences. Instead, relative permeabilities that are needed to predict fluid flow in air-NAPL-water-soil systems are normally estimated. The general approach is to extrapolate from two-phase relative permeabilities, which in turn may be measured directly on relevant samples or estimated from empirical correlations. Two commonly used empirical models in petroleum engineering to describe two-phase relative permeability are the Corey (1954)-type power laws and LET correlations (Lomeland et al., 2005). These functions are presented in the chapter *Water Retention and Characteristic Curve*.

Three-phase relative permeability under strongly water-wetting conditions

Investigators began to study relative permeability in air-NAPL-water systems in the mid-1950s, largely focusing on strongly water-wet conditions. Water and air (and gaseous phases in general) are the wetting and non-wetting phases, respectively, under strongly water-wet conditions irrespective of the presence of NAPL. In contrast, NAPL will preferentially wet the grains relative to gas, but will be repelled relative to water. Consequently, the relative permeabilities to water and air depend mainly on their respective saturations and saturation histories but the relative permeability to NAPL depends on the saturation of all three fluids and their history. We provide selected examples of each below.

Air relative permeability. Hysteresis exists in $k_x(S_x)$ relations primarily because of the entrapment of fluids with lesser wettability by fluids with greater wettability (see *Hysteresis* chapter for other causes). Because air is the non-wetting phase in an air-water, air-NAPL, or an air-NAPL-water system, it will be trapped by capillary forces when its saturation is decreasing, i.e., when pore space occupied by air is invaded by water or NAPL. As expected, laboratory measurements of $k_{rg}(S_g)$ clearly display hysteresis, with $k_{rg}(S_g)$ smaller in the direction of decreasing S_g below a critical S_g (e.g., blue, Fig. 6). The critical S_g presumably corresponds to the saturation at which some of the gas becomes discontinuous (cf. Figs. 2E and 3B). Note that two-phase and three-phase $k_{rg}(S_g)$ are approximately the same at the same S_g and direction of S_g change. Accordingly, $k_{rg}(S_g)$ in air-water-NAPL systems is conventionally approximated by the two-phase $k_{rg}(S_g)$.

Water relative permeability. In strongly water-wetting systems, physical reasoning suggests that water will not be trapped and, accordingly, $k_{rw}(S_w)$ is expected to display only a weak dependence on saturation history. Indeed, laboratory measurements of $k_{rw}(S_w)$ of strongly water-wetting sandstones in three-phase systems have been found to depend largely on the value of S_w and not whether S_w is increasing or decreasing (e.g., markers, Fig. 7). In contrast, in some two-phase systems at low S_w (≤ 0.6), $k_{rw}(S_w)$ at a given S_w is larger in the direction of increasing S_w (blue) than decreasing S_w (red) (lines, Fig. 7). While $k_{rw}(S_w)$ in Berea sandstone

Fig. 6 Relative permeability of a Berea sandstone core (A) and Bentheimer sandstone cores (B) to gas with two (solid lines: water-gas; all other lines: oil-gas) or three fluids (markers) present. Fig. 7 Relative permeability of a Berea sandstone core (A) and Bentheimer sandstone cores (B) to water with two (solid lines: water-gas; all other lines: water-oil) or three fluids (markers) present as reported in Oak, 1990 and Oak et al., 1990 (A) and Alizadeh and Piri, 2014 (B). Red and blue denote decreasing and increasing S_w , respectively. Data from: (A) Oak MJ, Baker LE and Thomas DC (1990) Three-phase relative permeability of Berea sandstone. *Journal of Petroleum Technology* 42(8): 1054–1061. doi: 10.2118/17370-PA; Oak MJ (1990) Three-phase relative permeability of water-wet Berea. In: *Proceedings, SPE/DOE Enhanced Oil Recovery Symposium, Tulsa, Oklahoma, April*. doi: 10.2118/20183-MS.; (B) Alizadeh AH and Piri M (2014) The effect of saturation history on three-phase relative permeability: An experimental study. *Water Resources Research* 50: 1636–1664. doi: 10.1002/2013WR014914.

appears to be slightly lower for a three-fluid system than the corresponding two-fluid (i.e., gas-water or NAPL-water) system at the same S_w for increasing S_w (blue lines and markers, Fig. 7A), the difference is generally interpreted to be negligible, and $k_{rw}(S_w)$ in air-water-NAPL-soil systems is conventionally approximated by the two-phase $k_{rw}(S_w)$.

NAPL relative permeability. NAPL is the wetting phase relative to air but the non-wetting phase relative to water. It is thus possible for gas to mobilize and displace oil that has been trapped by water. Consequently, and in contrast to k_{rw} , NAPL relative permeability is a function not only of its own saturation but also of the relative amounts of the other two fluids. Thus three-phase $k_{ro}(S_o)$ cannot be approximated by two-phase $k_{ro}(S_o)$ (e.g., Fig. 8, top row), and there can be large differences in NAPL relative permeability because of hysteresis.

Nonetheless, several salient features have been identified. When NAPL displacement is dominated by layer drainage and $S_w \ll S_o$, theory predicts that $k_{ro} \sim S_o^2$ (Fenwick and Blunt, 1998). $k_{ro}(S_o)$ of some gas-water-NAPL fluid systems indeed display a quadratic dependence at low S_o (e.g., Fig. 8A; see also Fenwick and Blunt, 1998); at higher S_o , the exponent is larger than 2. A $k_{ro} \sim S_o^2$ regime is not observed in other gas-water-NAPL combinations (e.g., Fig. 8B), although this may be due to limitations on the range of S_o considered.

Several empirical models have been proposed to predict relative permeability where all three fluids are flowing, with two most popular models in petroleum engineering being those of Baker (1988) and Stone (1970). Both models involve the extrapolation of two-flowing phase relative permeability data to three-flowing phase conditions. The model by Baker (1988) involves saturation-weighted interpolation between NAPL relative permeability in NAPL-water systems, k_{ro}^{ow} , and NAPL relative permeability in three fluid (i.e., water-NAPL-gas) systems at irreducible water saturation, $k_{ro}(S_{wi})$, at the three-phase S_o :

$$k_{ro}(S_o) = \frac{(S_w - S_{wi}) k_{ro}^{ow}(S_o) + (S_g - S_{gr}) k_{ro}(S_{wi}, S_o)}{(S_w - S_{wi}) + (S_g - S_{gr})} \quad (17)$$

where S_{gr} is residual gas saturation in the three-flow phase system. The model by Stone (1970) is given by:

$$k_{ro}(S_o) = S_{oe} \frac{k_{ro}^{ow}(S_w)}{1 - S_{we}} \frac{k_{ro}^{og}(S_g)}{1 - S_{ge}} \quad (18)$$

where

$$\begin{aligned} S_{oe} &= \frac{S_o - S_{or, \min}}{1 - S_{wi} - S_{or, \min}} \\ S_{we} &= \frac{S_w - S_{wi}}{1 - S_{wi} - S_{or, \min}} \\ S_{ge} &= \frac{S_g}{1 - S_{wi} - S_{or, \min}} \end{aligned} \quad (19)$$

and $S_{or, \min}$ is the minimum value of S_{or} under three-phase flow conditions; $S_{or, \min}$ may be predicted from S_{or} in water-oil and oil-gas systems by, e.g., saturation-weighted interpolation, or used as a fitting parameter (Kianinejad and DiCarlo, 2016). Note that it is not always possible to match the saturation history of the three-phase flow with those of $k_{ro}^{ow}(S_w)$ and $k_{ro}^{og}(S_g)$. If S_g is increasing

Fig. 8 Relative permeability of a Berea sandstone core (A) and Bentheimer sandstone cores (B) to NAPL with two (lines) or three fluids (markers) present. Lines in top row: water-NAPL drainage (green) and imbibition (grey); NAPL-gas drainage (red) and imbibition (blue). Markers: red and blue denote decreasing and increasing S_o , respectively. Bottom row only shows three-phase data; solid black line is $k_{ro} \sim S_o^2$. Data from (A) Oak MJ (1990) Three-phase relative permeability of water-wet Berea. In: *Proceedings, SPE/DOE Enhanced Oil Recovery Symposium, Tulsa, Oklahoma, April*. doi: 10.2118/20183-MS and Oak MJ, Baker LE and Thomas DC (1990) Three-phase relative permeability of Berea sandstone. *Journal of Petroleum Technology* **42**(8): 1054–1061. doi: 10.2118/17370-PA and (B) Alizadeh AH and Piri M (2014) The effect of saturation history on three-phase relative permeability: An experimental study. *Water Resources Research* **50**: 1636–1664. doi: 10.1002/2013WR014914.

and S_o and S_w are decreasing in the three-phase flow, one would choose $k_{ro}^{og}(S_g)$ measured in the same direction (i.e., increasing S_g and decreasing S_o). However, the correct choice for $k_{ro}^{ow}(S_w)$ is not clear, since S_w and S_o cannot change in the same direction at the same time.

Partitioning of NAPL components among the fluid and solid phases

NAPL components in soils are present in various forms. They can be dissolved in pore water or in a NAPL phase, or adsorbed on the grain surfaces. In addition, volatile components may be found in the gaseous phase. To predict the fate of NAPL components in the subsurface, the partitioning of the components between liquid, gaseous, and solid phases must be considered.

Fig. 9 illustrates the partitioning pathways in a soil-water-air-NAPL system (Newell et al., 1995). Mass transfer of NAPL components within strongly water-wet soil involves three main processes: (a) *volatilization* from the aqueous phase and NAPL into the gaseous phase; (b) *dissolution* from the gaseous phase and NAPL into the aqueous phase; and (c) *sorption* from the aqueous phase onto and into the solid phase. Because water coats the grains in water-wet media, gas-to-grain and NAPL-to-grain mass transfer are believed to be rare. Instead, NAPL components in the gas phase and the NAPL must first partition into the aqueous phase before adsorbing on grain surfaces.

Several different models have been used to describe the mass transfer of compounds between aqueous, gaseous, and solid phases in soil. Because many mass-transfer processes are assumed to occur much faster than the convective flow of the fluids, mass transfer is commonly modelled as being instantaneous and local equilibrium is assumed.

Fig. 9 Partitioning pathways between the four phases that may be found in the unsaturated zone. Solid arrows depict main pathways; dashed arrows depict less likely pathways. Modified from Newell CJ, Acre SD, Ross RR and Huling SG (1995) *Light Nonaqueous Phase Liquids. Ground Water Issue*. US EPA; Report No. EPA/540/S-95/500.

Distribution of NAPL components at local equilibrium

Soil-water partitioning (sorption) Sorption is the result of two mechanisms: *adsorption* onto the surface of grains and *absorption* into the internal volume (e.g., microporosity) of the grains. Under idealized conditions—where microporosity is limited, absorption is negligible, and conditions are steady—sorption equilibrium may be achieved relatively quickly. Equilibrium sorption of many organic, nonpolar chemicals can be described by a linear sorption isotherm of the form

$$C_s^\beta = K_d^\beta C_w^\beta \quad (20)$$

where C_s^β is the equilibrium sorbed concentration of NAPL component β [mass of sorbed chemical β per unit dry mass of soil], C_w^β is the equilibrium aqueous concentration of β [mass dissolved per unit volume of the aqueous phase], and the constant of proportionality K_d^β is the equilibrium soil/water partitioning (or distribution) coefficient for β [$L^3 M^{-1}$].

Where the mass fraction of organic carbon in the soil—a routinely measured property in the laboratory—is greater than $f_{oc} = O(0.1-1)$ wt%, sorption of NAPL components is controlled by the organic content of the soil and K_d^β can be estimated by:

$$K_d^\beta = f_{oc} K_{oc}^\beta \quad (21)$$

in which K_{oc}^β is the organic carbon partitioning coefficient of NAPL component β , which can be estimated from solubility data and molecular structure (see *Solute Transport* chapter for a table of K_{oc} values). In low f_{oc} soils, sorption onto inorganic surfaces becomes significant and $K_d^\beta > f_{oc} K_{oc}^\beta$ (Fitts, 2013 and references therein). A linear sorption isotherm assumes K_d^β is independent of concentration, which is not valid at high concentrations. More complex models and further discussion can be found in the *Organic Chemicals* chapter.

Water-air partitioning (volatilization) The partitioning of NAPL components between the gaseous phase and the aqueous phase is described by Henry's Law,

$$p^\beta = K_H^\beta C_w^\beta \quad (22)$$

where p^β is the partial pressure of NAPL component β in the gaseous mixture at equilibrium with the aqueous phase, C_w^β is the concentration of β in the aqueous phase [moles of β per unit volume of aqueous phase] and K_H^β [$atm m^3 mol^{-1}$] is the constant of proportionality known as Henry's Law constant. The partial pressures can be converted into concentrations of the NAPL components in the gaseous phase using, e.g., the ideal gas law, which yields:

$$C_g^\beta = \frac{p^\beta}{R T} = \frac{K_H^\beta}{R T} C_w^\beta \quad (23)$$

where C_g^β is the number of moles of component β volatilized into a unit volume of the gaseous phase, R is the ideal gas constant, and T is the temperature.

NAPL-air partitioning (volatilization) The partitioning of NAPL components between the gaseous phase and the NAPL is often described by Raoult's Law,

$$p^\beta = p_*^\beta x_o^\beta \quad (24)$$

where p^β is now the equilibrium partial pressure of NAPL component α in the gaseous mixture over the NAPL mixture, p_*^β is the equilibrium vapor pressure of the pure component β at the same temperature, and x_o^β is the mole fraction of component β in the NAPL mixture [moles of β /moles of all molecules in the NAPL phase]. The larger the value of p_*^β , the more volatile the component. As in Eq. (22) above, the ideal gas law can be applied to convert partial pressure to concentration, and Eq. (24) becomes:

$$C_g^\beta = \frac{p^\beta}{R T} = \frac{p_*^\beta}{R T} x_o^\beta \quad (25)$$

Since $x_o^\beta \leq 1$, Eq. (25) implies that the equilibrium concentration of each component β in the gaseous phase will be lower than if the NAPL was 100% β .

NAPL-water partitioning (dissolution) If the liquid phases both behave as ideal mixtures, an analogue of Raoult's Law may be used to describe the partitioning of NAPL components between a multicomponent NAPL mixture and the aqueous phase at equilibrium:

$$C_w^\beta = C_{w*}^\beta x_o^\beta \quad (26)$$

where C_{w*}^β is the aqueous solubility of pure component β (e.g., benzene), i.e., the concentration of β in an aqueous phase that is in contact and in equilibrium with pure liquid β [moles L^{-1}]. The more water-soluble components (i.e., one with larger C_{w*}^β) will partition into groundwater more readily than the less soluble components (e.g., larger molecular weight hydrocarbons) in the NAPL phase, which in turn implies that the NAPL phase will become enriched in the less soluble components over time. The range of values of C_w^β in 31 gasoline samples from Florida, United States can be found in Table II, [Cline et al., 1991](#).

Challenges

In a real system, several factors may give rise to deviations from Eq. (24). For example, the presence of highly water-soluble constituents (e.g., alcohols), or cosolvents, is known to enhance the aqueous solubility of NAPL compounds. Similarly, if mass transfer cannot be assumed to be instantaneous, rate-limited mass transfer needs to be used to describe changes in NAPL component partitioning. Rate-limited interphase mass transfer is often approximated by first-order kinetic relationships representing the combined effect of all physical nonequilibrium processes affecting the migration between phases. The driving force is the concentration gradient across the interfaces separating the phases. The interphase exchange rate per unit volume [$M T^{-1} L^{-3}$] for first-order dissolution of NAPL constituents into the aqueous phase is usually given by:

$$\frac{\partial}{\partial t} (\phi S_w C_w^\beta) = k_{wo}^\beta a_{wo} [C_{w*}^\beta x_o^\beta - C_w^\beta(t)] \quad (27)$$

where k_{wo}^β [$L T^{-1}$] is the mass transfer coefficient between the aqueous phase and NAPL mixture and a_{wo} [L^{-1}] is the specific interfacial area between the two phases per unit bulk volume. As shown in Eq. (27), NAPL dissolution rates are dependent on the interfacial contact area. The relation between rate-limited NAPL dissolution and interfacial area has been the focus of several research projects.

At first glance, Henry's Law and Raoult's Law appear to be the same. However, there is a difference. Ideal Henry's Law behavior is observed for dilute solutions (i.e., low concentrations of component β), while ideal Raoult's Law applies to a mixture that is nearly pure (high concentrations). The two are thermodynamically consistent; however, significant deviations are frequently observed at intermediate concentration (mole fraction) ranges.

More broadly, the presence of NAPL in the soil is believed to render soils mixed-wet, with the grain surface in the middle of NAPL-invaded pores rendered less hydrophilic or even hydrophobic relative to surfaces in pores that remain water or air-filled. Under such conditions, direct mass transfer from NAPL to the solid phase may no longer be negligible. Similarly, near the top of the unsaturated zone where liquid saturation is sufficiently low, sorption from the vapor phase may be significant (see, e.g., [Unger et al., 1996](#) for a discussion). This is a topic for future work, involving high resolution imaging and sophisticated post-processing techniques that can resolve NAPL layers in mixed-wet systems.

Summary/outlook

Immiscible fluids are ubiquitous in the subsurface, occurring naturally (vadose zone) or because of human activity (NAPL contamination). Field-scale simulation models have been developed to predict the distribution and migration of immiscible fluids in the subsurface and changes to their composition. These simulators use empirical relationships between relative permeability and capillary pressure and phase saturations, which result from complex processes and are therefore difficult to estimate accurately, particularly where the pore space is occupied by three distinct phases. Many empirical correlations have been proposed, but they have limited physical bases and our ability to select the appropriate correlation for a given site is unsatisfactory. Indeed, for non-idealized wetting conditions expected in real soils, we lack both laboratory observation and predictive models. Furthermore, challenges remain in upscaling to field scale and simulating the flow field in heterogeneous porous media which is necessary for quantifying the fate and transport of immiscible fluids at system scales.

Emerging areas of research to address these gaps in knowledge include new closure equations based on detailed information of pore structure extracted from μ CT imaging. Recently the wider availability of μ CT has enabled detailed studies of immiscible fluids at the micron-scale. These relatively new data sets provide direct insight into pore-scale processes and can be used to improve the relationships used in field-scale numerical models. The theoretical framework exists, but experimental data to validate it and to guide its revision are still lacking.

Abstract

The movement of water across the soil surface is termed overland flow. Too much overland flow can cause major flooding, potentially causing damage to property and loss of life. While it is generally taught that runoff events occur when rainfall intensity exceeds the soil infiltration capacity, the most significant overland flow occurs after a large amount of rain over several days. The soil profile becomes saturated, and the rainfall cannot infiltrate and runs off. Therefore, the water stored in the watershed is a better predictor of overland flow than infiltration capacity. Best management practices that consider the runoff areas near streams are more effective than those implemented on the hillsides.

Key points

- Overland flow can cause major flooding, damage to property and loss of life.
- Most large floods are caused by saturation excess overland flow, where the soil becomes saturated, and the precipitation cannot infiltrate anymore and runs off as overland flow.
- Potential watershed storage before the rainstorm is a better indicator of the amount of overland flow than infiltration capacity.
- Infiltration capacity in well vegetated areas is usually greater than most rainfall intensities.
- Best management practices placed at runoff source areas near streams are more effective than those installed on the hillsides.

Introduction

Overland flow describes the runoff of rain before entering a stream channel without interacting with the groundwater. Commonly two mechanisms are identified for generating overland flow: infiltration excess and saturation excess. Infiltration excess runoff is defined as the process where runoff is generated when the rainfall intensity exceeds the soil infiltration capacity. Horton, (1933, 1939) measured it while performing experiments in 3.6 m long runoff plots. Hence it is referred to as ‘Hortonian runoff’. Hortonian flow is common during storms with very high rainfall intensities in arid and semi-arid areas (where significant soil crusting and surface sealing occurs), during rain events, irrigated fields, and in urban areas (Dunne and Leopold, 1978).

Early work

The Hortonian runoff concept does not meaningfully explain storm runoff in humid and sub-humid regions with well-structured soils where the infiltration capacity is greater than the average rainfall intensity (Hewlett and Hibbert, 1967; Dunne and Black, 1970). Runoff is generated in areas that are or become saturated during a rainfall event. This process is termed ‘saturation-excess

overland flow'. Unlike Hortonian flow, where overland flow can be clearly defined as water running over the surface, overland flow in saturated areas is less distinct. Overland flow may partially flow laterally through topsoil (hence the term throughflow coined by [Kitkby and Chorley, \(1967\)](#), cited by [Dunne and Black \(1970\)](#) in areas where the soils are saturated. In undisturbed forests ([Hewlett and Hibbert, 1967](#); [Sidle et al., 2000](#)) and abandoned grasslands ([Lyon et al., 2006](#)), all the flow is throughflow and overland flow is only visible over a short distance of the total flow path. [Hewlett and Hibbert, 1967](#)) wrote, 'Above the zone of saturation, we may regard such movement (i.e., lateral flow) as due to thickening of the water films surrounding soil particles and a resulting pulse in water flux as the saturated zone is approached'. [McDonnell \(2009\)](#) notes that Hewlett and Hibbert lacked any discussion of preferential flow paths. It should not be a surprise, since the notion of preferential macropore flow was only introduced in the late 1970s and early 1980s ([Bouma and Dekker, 1978](#); [Beven and Germann, 1981](#)). Thus the "thickening of the films" of Hewlett and Hibbert means that the water fills the macropores and pipes, greatly enhancing the conductivity of the soil. Consequently, throughflow occurs only when the soil becomes saturated due to a high groundwater table or a (shallow) layer restricting the downward percolation and forms a perched water table. When the soil is dryer, only the smaller pores hold the water. All early publications agree that contributions to overland flow from hillslopes without a perched water table are small during a rainstorm. On theoretical grounds, [Freeze and Witherspoon \(1968\)](#) supported this argument that water involved in the runoff event is only generated near and in the saturated area. Only over longer periods is the groundwater table affected by flow from the hillslopes and the amount of overland flow originating from the saturated area during rainfall events. Thus, connectivity in the landscape between areas, which are sources of runoff, depends on whether the soil profile is sufficiently wet so that water can be transported either overland or through large pores and pipes and along the soil-bedrock interface ([Torres et al., 1998](#)).

Saturated areas occur in the landscape where the incoming flow (both rainfall and lateral flow from upslope) is greater than water flowing out as lateral flow due to a reduction in slope, soil depth or hydraulic conductivity ([Beven and Kirkby, 1979](#); [Beven, 2001](#)). Under these conditions, the water table will eventually reach the surface given sufficient rain. Once saturated, any additional rainfall (irrespective of intensity) becomes overland flow. Areas prone to saturation occur at the bottom of slopes, usually in topographically converging regions with a high groundwater table or on hillsides with a hard pan (fragipan) at shallow depth ([Fig. 1](#)).

Overland flow from these saturated areas consists of direct runoff and return flow. Direct runoff originates from rain falling on the saturated area and running off as overland and lateral flow ([Hewlett and Hibbert, 1967](#)). Return flow occurs after the rain stops when the soils drain from saturation to a quasi-equilibrium moisture content, when all large pores are empty and the hydraulic gradient in the vertical direction is constant ([Brindt et al., 2022](#)).

The quasi-equilibrium moisture content is defined, similarly to field capacity of well-drained soils, as the moisture content at which the direct drainage is negligible. While for well-drained soils, field capacity is reached after saturating a soil when the unsaturated hydraulic conductivity becomes limiting, for soils with a high water table or fragipan at shallow depth, the vertical flow stops when the hydraulic gradient becomes constant with depth. The latter occurs when the matric potential decreases linearly with height above the water table, with the same quantity as the gravity potential increases with height. Therefore, the moisture content at equilibrium conditions with height can be found through the soil moisture characteristic curve ([Brindt et al., 2022](#)). If the soil is sloping, lateral flow occurs until the large pores are empty (defined as pores greater than 0.3–0.8 mm in diameter), when the conductivity of the soil matrix is one or two orders smaller than saturated hydraulic conductivity.

During periods of rainfall, the soil wets up and reaches saturation. As the rain continues, the area of saturated soil expands, and the overland flow per unit of rainfall will increase. Conversely, dry periods will decrease the extent of the saturated area, and the soil might dry out, depending on its location in the landscape. Hence the term 'variable source area' (VSA) comes with the expanded saturated area ([Dunne and Leopold, 1978](#)). The extent of the saturated area is illustrated in [Fig. 2](#) for the Catskills in upstate New York, where potential evaporation exceeds average rainfall during the summer and potential evaporation is less than precipitation during the winter ([Walter et al., 2000](#)).

Fig. 1 Incidence of saturation-excess hydrology: 1, shallow soil; 2, convergence area; and 3, decreasing downhill slope. VSA, variable source area. http://soilandwater.bee.cornell.edu/research/VSA/processes/processes_sat.html

Fig. 2 Seasonal changes of saturated areas (variable source areas) in a watershed in New York state. Color denotes areas more or less prone to saturation (Walter et al., 2000).

Experimental—Overland flow and watershed storage considerations

An interesting case study on saturation excess overland flow is the 95 ha Debre Mawi watershed near Lake Tana in Ethiopia. In this watershed, discharge was observed for 9 years from 2010 to 2018 at the outlet and in 4 small watersheds nested within. In the second and third years, the government installed, with the help of the farmers, soil and water conservation structures consisting of 60 cm deep and 50 cm wide infiltration furrows covering 70% of the watershed area (Mhired et al., 2020). These furrows were filled with soil within 2–3 years and were ineffective during the last 4 years of the case study. The area of Eucalyptus trees increased 10-fold to 5% of the watershed area in 2018 from 0.5 ha of small eucalyptus trees in 2010.

Yearly rainfall in the Debre Mawi watershed is around 1200 mm/year, of which 80% falls during the rain phase from the beginning of June to the middle of September. Over the study period, annual rainfall increased on average by 23 mm/year. Once the topsoil dries out during the dry phase, actual evaporation is negligible. Eucalyptus, unlike native trees, only transpire during the dry phase. Because Eucalyptus was planted in small woodlots, they transpire approximately twice the potential evaporation rate (about 10 mm/day) during the dry monsoon phase (Enku et al., 2020).

In the Debre Mawi watershed, saturation excess overland flow is generated from the valley bottom once sufficient rain has fallen. A hillside in the Debre Mawi watershed is shown in the photograph of Fig. 3. The grass is in the foreground, and cropland is shown further upslope. Two piezometers, P9 and P8, were installed in the grassland and one piezometer P7 in the cropland in 2018. The graph in Fig. 3 shows the water table depths after the piezometers were installed on July 15. In the grassland, the water table was at the surface from the first week of August until the middle of September. The water table in the cropland (piezometer P7) only increased slightly in the middle of July after a 50 mm rainfall. A volcanic dike perpendicular to the slope caused the high water table in the grassland that forced the water to the surface. This area was too wet to grow crops. Only higher up the slope, could crops be grown, where the soils were sufficiently drained, as shown by the groundwater depth readings in P7.

The runoff coefficients for the overland flow for all storms with rainfall above 8 mm are shown in the graph in Fig. 3. Storms on consecutive days were combined. The overland flow was minimal before July 15, when the water table rose and decreased rapidly after September 15 with the falling water tables in the grassland. This demonstrated clearly that overland flow was dependent on the degree of saturation in the watershed. Degraded soils that have a slowly permeable layer at 20–80 cm depth also generate overland flow from the hillside.

The effect of the increasing land area of eucalyptus trees on annual runoff at the outlet of the watershed was investigated over 9 years. We plotted the annual runoff coefficient instead of runoff to remove some of the annual rainfall variability (Fig. 4). The coefficient is defined as the yearly overland flow divided by the rainfall during the rain phase. In addition, we plotted in Fig. 5 the cumulative rainfall for 3 mm of runoff to occur. Annual runoff coefficients trended downward with the increased acreage of mature eucalyptus trees (Fig. 4).

The reduction in yearly runoff is caused by an increase in cumulative rainfall before significant runoff starts (Fig. 5). The explanation is as follows. Since runoff is generated by saturation excess runoff, the watershed needs to “fill up” before any significant overland flow can occur (Tilahun et al., 2016). The storage is depleted during the dry phase. The increased land area of eucalyptus trees decreases the soil storage to a greater degree because deep roots can reach a greater portion of the water. Consequently, more

Fig. 3 Photograph of a hillslope in the Debre Mawi from the top watershed divide with cropland to the bottom with grassland where it drains. The cropland looks small, but the length is about four times that of the grassland; The graph shows the groundwater table depths for the piezometers in the grassland (P8, P9) and the cropland (P7) and runoff coefficients at the watershed outlet.

Fig. 4 Annual runoff coefficient (i.e., quotient of annual runoff and annual rainfall in the monsoon rain phase) for the Debre Mawi watershed from 2010 to 2018.

Fig. 5 Amount of precipitation from the beginning of the rain phase to cause the first 3 mm of cumulative runoff at the outlet for the 95 ha Debre Mawi watershed.

precipitation is needed to fill up the depleted storage. The implication is that overland flow is decreasing by the amount that evaporation is increasing. Thus, a fixed amount of rainfall is needed each year to fill up the storage. It means that if the rain decreases, the runoff will be less by the same amount and not by a fraction, as would be the case if infiltration excess is the primary runoff mechanism. It also explains some of the variability around the trendline in Fig. 5. For example, 2015 had the least rainfall of the 9 years and the lowest runoff coefficient.

Overland flow models

Modeling overland flow with the SCS-CN

Infiltration excess type models predict runoff when the rainfall intensity exceeds the infiltration capacity of the soil or, more often, use the Soil Conservation Service Curve Number method (SCS-CN) as interpreted in the SCS handbooks. In this approach, curve numbers are assigned based on soil type and plant characteristics that determine the infiltration rate in the soil.

Although the SCS-CN was construed as an infiltration excess model, it is more likely to describe saturation excess runoff. This is because Victor Mockus developed the SCS-CN equation in the 1950s and 1960s to produce rainfall-runoff curves of a type found in natural watersheds. The watersheds referred to by Mockus are in the Appalachian mountains where saturation excess dominates.

It can be shown theoretically that the SCS-CN method is based on saturation excess by taking the derivative of the discharge with respect to the precipitation. The derivative is equal to the extent of the saturated portion A_s of the watershed when one assumes that rainfall runs off from the saturated area and infiltrates from unsaturated soil (Steenhuis et al., 1995). It can be expressed as

$$A_s = 1 - \frac{\bar{S}^2}{[P + \bar{S}]^2} \quad (1)$$

where P is the effective rainfall (total precipitation minus the amount that brings the soil to the equilibrium moisture content) and $\bar{S}$ is the average storage in the watershed, which is related to the curve number.

Based on the amount of rain required to saturate the soil, the available storage before runoff occurs, σ , can be expressed as a function of the area that becomes subsequently saturated (Schneiderman et al., 2007)

$$\sigma = \bar{S} \left[\sqrt{\frac{1}{1 - A_s}} - 1 \right] \quad (2)$$

where σ is the available storage in the soil (or the amount of water needed to bring the soil to saturation from field capacity) as a function of the area that becomes subsequently saturated, A_s . Hence $A_s = 0$ for the wettest area with the highest topographic index and $A_s = 1$ for the area with the lowest topographic index.

The propensity to saturate can be found by ranking the landscape according to the topographic index defined (Beven and Kirkby, 1979) as the volume of water delivered per unit contour length divided by the ability of the soil profile to transmit the flow (Beven and Kirkby, 1979). Thus, the extent of the saturated area can be found from the total effective rainfall and average storage in the watershed. The latter can be linked with a curve number.

Saturation excess runoff models

The SWAT (Soil and Water Assessment Tool) model is likely the most widely used worldwide because it is open source and has an extensive literature database that makes it easy to use. However, because it predicts runoff according to infiltration excess, the runoff

source areas are not the same as in a watershed with saturation excess runoff. Changing the location of the runoff areas can be easily accomplished by redefining the soils according to the topographic index in wetness classes. By ranking the wetness classes according to the topographic index, the available storage can be calculated, and runoff can be determined as the amount of rain that cannot be stored in the soil. Models such as SWAT-VSA (Easton et al., 2008) and SWAT-wil (Steenhuis et al., 2019) are based on this principle. SWAT-HS (Hoang et al., 2017) introduces a surface interflow reservoir to accommodate flow between wetness classes.

Another model to predict the saturated-excess overland flow is the TOPMODEL. It is based on calculating a groundwater table height. When the groundwater intersects with the soil surface, runoff occurs. In the TOPMODEL, the assumption is made that a groundwater table underlies the watershed, which is unrealistic for many mountainous areas. However, since most of the saturated areas occur near streams, this limitation is not severe as a groundwater table is present in these areas. An alternative method for simulating saturated areas in a sloping watershed with a hardpan is the DHSVM (Wigmosta et al., 1994) and SMR (Frankenberger et al., 1999) models. In these models, water is routed by interflow from one cell to the next.

Water quality impacts of saturation excess overland flow

Water quality of overland flow depends on the soil chemical concentration at the location where it is generated. Therefore, best management practices to improve water quality should consider the location of surface runoff. Many practices aimed at reducing contaminant transport, such as terraces, soil bunds and infiltration furrows implemented on the hillsides, are based on Hortonian concepts. However, the effectiveness of these practices is diminished where Hortonian processes are not governing runoff generation.

Wherever VSA hydrology is a dominant process, there will be regions within a watershed that are more susceptible to producing runoff and delivering it to surface water bodies than other regions. These areas can be considered hydrologically sensitive areas (HSA). Recognizing the existence of HSAs allows watershed-scale water quality efforts to be focused on those areas where HSAs coincide with land uses that potentially contribute pollutants (Walter et al., 2000; Rittenburg et al., 2015). The intersection of an HSA and a pollutant loading area is called the 'critical management zone.' The best management practice for this area would be limiting or prohibiting polluting activity from these HSAs. A contrasting approach is finding methods and means of eliminating the hydrological sensitivity of the critical zones, although recent research suggests attempts to remove hydrologic sensitivity through drainage practices may reroute pollutants from overland flow to subsurface flow, with little reduction in concentration at a downstream target location. In either case, the HSAs warrant primary attention when preserving or improving water quality.

One example in upstate New York, where HSAs play a role in management practices, is whether dairy operators should spread manure on steep slopes or in flat areas. The past dogma was to avoid manure spreading on steep slopes and instead maximize spreading in flat areas. Under Hortonian flow, steep areas might arguably produce the most rapidly moving runoff and, therefore, the greatest potential for erosion and transport of manure. However, saturation excess overland flow is identified as the dominant process, where all rainwater infiltrates on the sloping lands and drains very rapidly, resulting in almost no substantial runoff (Hoang et al., 2019). Conversely, the flat areas, especially at the base of hillslopes, are especially prone to saturation and, thus, prone to runoff generation (Walter et al., 2000; Rittenburg et al., 2015). Fig. 6 shows manure deposition in the wrong place from an HSA standpoint. A manure-spreading policy more consistent with the recognized hydrology would promote spreading manure higher up in the watershed and minimize spreading on low, flat areas susceptible to runoff generation (Hoang et al., 2019).

Conclusion

While infiltration excess runoff is generally considered the main cause of runoff, saturation excess on vegetated surfaces is the cause of many large floods. Especially during large storms, rainwater fills up the soils, and any additional rain becomes runoff. It is therefore essential to consider both runoff processes in the design of flood control structures and best management practices to improve water quality.

Abstract

Soil structure induces vertical or horizontal direction dependency in water flow and mechanical behavior. These effects are exacerbated by anthropogenic induced plate structure formation, where soil deformation due to mechanical loads can lead to a distinct horizontal anisotropy of the soil pore system. This promotes surface runoff and thus increased soil erosion and may reduce biomass productivity. The direction-dependent differences in intensity parameter (i.e., hydraulic conductivity, air-permeability) due to soil deformation can be effectively linked to the pore size distribution and continuity.

Key points

- Direction-dependent differences in soil mechanical or transport properties are strongly related to the pore size distribution and continuity
- The preferential direction of air or water transport in soil is horizontal under compaction and vertical under cracking.
- Prismatic soil structure indicates slightly greater shear resistance in vertical than horizontal directions
- Platy soil structure indicates slightly greater shear resistance in horizontal than vertical directions

Introduction

Soil physical properties may vary from one location to another (heterogeneity), as well as from one direction to another at the same location (anisotropy). While the directional behavior (isotropy or anisotropy) of soil hydraulic conductivity is of primary importance in analyzing rates and directions of water flow and solute transport in the vadose zone, in terms of mechanical properties it is of great relevance in evaluating soil deformation processes since each mechanical stress applied to the soil surface results in a 3-dimensional stress propagation.

The directional behavior of soil physical properties governs not only hydrologic processes (e.g., infiltration, recharge, evaporation, and runoff) but also soil aeration and root growth. It has been documented that the induced mechanical load can result in a platy soil structure when the induced mechanical stresses exceed the stability of the soil structure. The latter results in direction-dependent behavior of e.g., air permeability and hydraulic conductivity due to a predominantly higher pore continuity and connectivity in a horizontal than in a vertical direction. At the same time, since the mechanical strength also has direction-dependency, root growth can be impeded vertically, affecting potential soil exploration. The following chapter examines both the direction dependency of hydraulic and mechanical properties in soils, considering theoretical aspects, results of different studies, and new methodologies used to evaluate direction dependent processes in soils.

Anisotropy of air and water flow in the vadose zone

Soils generally consist of several and differently structured horizons with direction-dependent properties due to the textural composition and soil aggregate formation (Dörner and Horn, 2006). Even in the same layer, the heterogeneous arrangements of

Fig. 1 Effect of swell shrinkage processes on the geometry factor, r_s , as an expression of the isotropy or anisotropic volume changes (Peng and Horn, 2007).

soil particles and aggregates due to anthropogenic and pedogenetic effects result in a discrepancy of pore continuity and tortuosity between the different directions (Beck-Broichsitter et al., 2020c). The resulting anisotropy is generally influenced by soil structure (e.g., platy, columnar, etc.), therefore exhibiting a pattern of pores with a distinct directional bias. Such heterogeneous soil structure has been found to influence soil deformation (Peng and Horn, 2007), soil strength and transport processes (Dörner and Horn, 2006).

The anisotropy of air and water flow through unsaturated porous media can vary depending on time, land use management, degree of saturation, and annually varying wetting and drying cycles, biological activity, or anthropogenic impacts (Reszkowska et al., 2011). Air and water fluxes in soils are mostly multidimensional and their direction-dependency is strongly reliant on aggregate formation and orientation, as well as pore size distribution (Horn and Smucker, 2005; Dörner and Horn, 2006). In addition, soil compaction can increase the probability of preferential flow through existing or emerging macropores produced by pore system restructuring (i.e., crumbly to platy). For instance, topsoil compaction may cause a platy structure to form, but over time it may change to crumbly through swelling-shrinkage or freezing-thawing cycles (Jarvis, 2007) or deep-rooting plants (Beck-Broichsitter et al., 2020c) (Fig. 1).

Swelling and shrinkage can produce anisotropic processes (Fig. 1). Starting from a completely homogenized saturated soil, the initial vertical anisotropic shrinkage during drying is followed by a primarily horizontal anisotropic swelling (Hartge and Horn, 2016). Repeated shrinkage and swelling patterns pass through a complete isotropic volume change, but anisotropy can occur from strengthening that induces primarily horizontal volume changes. Dörner and Horn (2009) also demonstrated these processes for various soils and geological origin with the help of the geometry factor, r_s to measure anisotropy.

A platy soil structure is typical for engineered barriers (Beck-Broichsitter et al., 2020b) and mechanical-induced topsoil compaction of arable fields (Schlüter et al., 2018). Another cause of direction dependent fluxes in arable soils is from subsoil compaction. Fig. 2 presents the results of water flow modelling in a structured Stagnic Luvisols in Northern Germany under arable management (Dörner and Horn, 2006). Anisotropic conditions of the saturated hydraulic conductivity occurred due to plow pan formation that led to a deviation of the water flow vectors, generating preferential flows parallel to the slope at 15–25 cm depth. In contrast, in well-aggregated soil, isotropic conditions generally occur, where no statistically significant differences in the hydraulic conductivities between the vertically and horizontally oriented samples are found (Reszkowska et al., 2011).

Anisotropy of gas diffusivity, air-permeability, and air-filled porosity

Soil aeration depends on gas diffusivity, D_p , and air-permeability, k_a , which is largely affected by the air-filled porosity, θ_a . Whereas D_p and k_a describe the intensity of transport, θ_a describes the capacity of transmissive pores. They are therefore referred to as intensity and capacity parameters, respectively. All these parameters are a function of initial soil structure and stability (Beck-Broichsitter et al., 2020a), pore continuity, connectivity, and tortuosity (Schjønning and Koppelgaard, 2017), degree of compaction, volumetric water content, and pore size distribution (Chief et al., 2008).

Gas diffusivity and air-permeability are tensors that can indicate isotropic or anisotropic behavior due to direction-dependent D_p - and k_a -values in three spatial dimensions (Dörner and Horn, 2006). The one-dimensional advective steady-state air flow in soils can be described by Darcy's law as,

Fig. 2 Water flow vectors (v) with (A) isotropic conditions of saturated hydraulic conductivity and (B) anisotropic saturated hydraulic conductivity at the plow pan depth (15–25 cm). SS-LL: Stagnic Luvisol, YKn: Anthrosol derived from colluvic material (Dörner and Horn, 2006). The soil profile can be seen in Fig. 5.

$$\nabla^2 \left(\frac{k_a}{\eta} p_e \right) = 0 \quad (1)$$

where η is the air viscosity (Pa s^{-1}), k_a is the air permeability (m^2), p_e (Pa) is the differential pressure from atmospheric pressure, p_a (Pa), and at steady-state ($p_e < p_a$).

The three-dimensional air flow in soils can be numerically solved as (i.e., Chief et al., 2008),

$$\frac{k_{ax}}{\eta} \left(\frac{\partial^2 p_e}{\partial x^2} \right) + \frac{k_{ay}}{\eta} \left(\frac{\partial^2 p_e}{\partial y^2} \right) + \frac{k_{az}}{\eta} \left(\frac{\partial^2 p_e}{\partial z^2} \right) = 0 \quad (2)$$

The anisotropy ratios, AR, can be expressed in a direction-dependent form (Table 1), where θ_{axi} , k_{axi} , θ_{aBxi} are air-filled porosity, air permeability, and blocked-air-filled porosity in x direction, and θ_{azi} , k_{azi} , θ_{aBzi} are the corresponding parameter in z direction, while assuming x direction = y direction (Ball et al., 1988, 2001).

For sandy, coarse-loamy, and fine-silty arable soils and in a bulk density range between 1.3 g cm^{-3} and 1.5 g cm^{-3} , the k_a -derived anisotropy ratios can vary between 0.06 and 15.8 (Chief et al., 2008). In Fig. 3, for loamy sand with crumbly structure in a bulk density range between 1.15 g cm^{-3} and 1.25 g cm^{-3} , the AR_{ka} values can vary between 0.5 and 1.4, while a bulk density range between 1.75 g cm^{-3} and 1.85 g cm^{-3} and a platy structure result in AR_{ka} values between 1.5 and 2.2 (Beck-Broichsitter et al., 2020a). Furthermore, anisotropy conditions might introduce significant errors of up to two orders of magnitude in on-site intrinsic permeability measurements (Chief et al., 2008).

The blocked air-filled porosity in both directions can reach up to $1/4$ of a soil's total porosity (Dörner and Horn, 2006; Beck-Broichsitter et al., 2020a). In aggregated soils, lower θ_{aB} values can be expected along the dominant axis presenting an anisotropic behavior. The blocked-air-filled porosity is the pore space that does not take part in convective air transport (Ball et al., 1988).

In arable used soils, the $AR_{\theta_{aB}}$ values can vary between 0.3 and 0.9 in coherent, angular-blocky, and subangular-blocky topsoil layer ($\leq 35 \text{ cm}$ depth) and up to 12.0 in platy-structured plow pans, while subsoil layers ($> 35 \text{ cm}$ depth) with subangular-blocky

Table 1 Standard formulas calculating the air-filled porosity, θ_a , the air permeability (μm^2), k_a , and the blocked air-filled porosity, θ_{aB} ($\text{cm}^3 \text{ cm}^{-3}$), at each measurement step (i.e., saturation, water content, pore size distribution), I, respectively in x and z direction, while assuming $x = y$ (Ball et al., 2001; Dörner and Horn, 2006).

Standard formulas	Anisotropy ratios
$\theta_a = \left(1 - \frac{\rho_b}{\rho_s} \right) - \theta_v$	$AR_{\theta_a} = \sum_{i=1}^n \frac{\Delta \theta_{axi}}{\Delta \theta_{axi}}$
$k_a = M \cdot \theta_a^N$	$AR_{k_a} = \sum_{i=1}^n \frac{\Delta k_{axi}}{\Delta k_{axi}}$
$\theta_{aB} = 10^{\frac{(-\log(M))}{N}}$	$AR_{\theta_{aB}} = \sum_{i=1}^n \frac{\Delta \theta_{aBxi}}{\Delta \theta_{aBxi}}$

N and M are empirical parameter (Ball et al., 1988), ρ_b (g cm^{-3}) is the dry bulk density, ρ_s (g cm^{-3}), is particle density, θ_v the volumetric water content ($\text{cm}^3 \text{ cm}^{-3}$), and AR_{θ_a} , AR_{k_a} , and $AR_{\theta_{aB}}$ the corresponding anisotropy ratios.

Fig. 3 Air permeability, k_a (μm^2), versus air-filled porosity, θ_a ($\text{cm}^3 \text{cm}^{-3}$), of a loamy sand with ρ_b between 1.15 g cm^{-3} and 1.25 g cm^{-3} in 5 cm depth, and ρ_b between 1.75 g cm^{-3} and 1.85 g cm^{-3} in 20 cm, 50 cm, and 80 cm depths, samples taken in vertical (ver) and horizontal (hor) direction (Beck-Broichsitter et al., 2020a). The dashed lines indicate the confidence interval CI: 95%.

structure tend to $AR_{\theta_{aB}}$ values between 0.6 and 5.8 (Dörner and Horn, 2006). A similar tendency is shown by Beck-Broichsitter et al. (2020b) with $AR_{\theta_{aB}}$ values < 1.0 for crumbly structured topsoils and $AR_{\theta_{aB}}$ values up to 6.8 for platy structured subsoils.

The one-dimensional diffusive gas flux in soils is controlled by the soil-gas diffusion coefficient, D_p , outlined as soil-gas diffusivity D_p/D_0 and can be expressed with a predictive model (i.e., Moldrup et al., 2013) as,

$$\frac{D_p}{D_0} = p\theta_a^\chi \left[\frac{\theta_a}{\theta_T} \right]^{T_a} \quad (3)$$

where θ_T is the total porosity ($\text{m}^3 \text{m}^{-3}$), p , χ , and T_a are model parameters.

The typical fitting parameters for pure sand and sand size fractions are $p = 1$ and $\chi = 4/3$, and $p = 1$, while for soils with total porosities up to $0.5 \text{ cm}^3 \text{cm}^{-3}$ for fractured, clayey soils $\chi = 2$ (Moldrup et al., 2013).

The three-dimensional soil gas diffusion assuming quasi-steady state behavior (Maier et al., 2020) can be numerically solved by Fick's law as,

$$\frac{D_{px}}{D_0} \left(\frac{\partial^2 C}{\partial x^2} \right) + \frac{D_{py}}{D_0} \left(\frac{\partial^2 C}{\partial y^2} \right) + \frac{D_{pz}}{D_0} \left(\frac{\partial^2 C}{\partial z^2} \right) = 0 \quad (4)$$

where D_{px}/D_0 is the soil-gas diffusivity in x direction, D_{py}/D_0 is soil-gas diffusivity in y direction. Assuming $D_{px}/D_0 = D_{py}/D_0$, the anisotropy ratio can be calculated as,

$$AR_{\frac{D_p}{D_0}} = \sum_{i=1}^n \frac{\frac{D_{px}}{D_0}}{\frac{D_{pz}}{D_0}} \quad (5)$$

It must be remembered that soil gas diffusivity in multidimensional porous media depends on the rigidity of soil structure (Horn et al., 2019) and therefore the tortuosity and pore connectivity is affected by swelling and shrinkage or freezing and thawing cycles (Villagra et al., 2020), even in subangular blocky and platy structured soils.

Anisotropy of saturated and unsaturated hydraulic conductivity and permeability

The possibility to predict the soil hydraulic properties on various scales from small aggregates of few μm with an intra-aggregate pore system up to the hillslope scale of square kilometers (Dusek and Vogel, 2018) depends on the structure of the pore system. Of major importance is the presence and distribution of macropores (MaP) with $d > 0.3 \text{ mm}$, structural pores or inter-aggregate pores

Fig. 4 Pore size distribution as function of the slope of the water retention curve, $\Delta Se \Delta h^{-1}$, of a Haplic Luvisol profile (Ap/Ah, E and E/Bt, Btg, CBkg, and C horizons) in Fig. 1 with an alfalfa and grass plot in 25 cm and 45 cm depth in vertical (ver) and horizontal (hor) directions (Beck-Broichsitter et al., 2020c). The h-value of -10 hPa (about 9.81 cm) was assumed as boundary between the macropores MaP ($h_1 \geq -10$ hPa), and wide coarse pores wCP ($-10 > h_2 \geq -60$ hPa).

including wide coarse pores (wCP) with $0.3 \geq d > 0.05$ mm, and textural pores known as matrix, intra-aggregate, and inter-particle pores including narrow coarse pores (nCP) with $0.05 \geq d > 0.01$ mm, medium pores (MP) with $0.01 \geq d > 0.0002$ mm, and fine pores (FP) with $d \leq 0.0002$ mm (Horn and Smucker, 2005).

The pore size distributions in Fig. 4 are characterized by direction-dependent differences in the structural peaks between water potentials of -10 hPa and -60 hPa, and the matrix peaks at around -100 hPa and at around -5000 hPa. Pedogenesis of a soil profile results in greater vertical than horizontal cracks, producing anisotropy in pore size distribution between vertical and horizontal directions (Fig. 4).

An anisotropy ratio (AR) can be defined as the ratio of Ks-values obtained in vertical (ver) and horizontal (hor) directions (Beck-Broichsitter et al., 2020a, b) as,

$$AR_{Ks} = \frac{K_{s_{hor}}}{K_{s_{ver}}} \quad (6)$$

Eq. 6 describes not only these flux differences in vertical and horizontal direction, but it is also important for determining the unsaturated hydraulic conductivity (Hartge and Horn, 2016).

In Fig. 5, the saturated hydraulic conductivity, Ks, shows structure-dependent differences but the AR_{Ks} values also strongly depend on land use and the clay content. For grassland sites, AR_{Ks} values >1 are most obvious for the topsoil, while the subsoil horizons of arable sites show comparatively more pronounced AR_{Ks} values, also depending on the clay content (Horn et al., 2019).

Fig. 5 Conventional tilled Stagnic Luvisol derived from glacial Weichselian till in Northern Germany with different structure types. Anisotropy ratios (arithmetic mean $\pm$ standard deviation) of the saturated hydraulic conductivity, AR_{Ks} , in five different soil horizons (Horn et al., 2019).

Platy structures show mostly dominating horizontal fluxes caused by trampling, grass harvesting, and slurry application with heavy machinery through stress induced particle rearrangement.

In summary, crumbly formed or subangular blocky structured soil horizons mostly indicate isotropic fluxes (Hartge and Horn, 2016), while prismatic structured soils exhibit a predominantly vertical flow caused by the development of secondary pores (shrinkage cracks) or biopores (Uteau et al., 2013) in contrast to a platy structure with predominantly horizontal flow.

In Fig. 6, anisotropy of Ks values, especially in the subsoils under arable land use for a range of soils can be explained by the development of a platy soil structure because of the management (tillage). Sandy soils (Podzols) show only minor anisotropy effects. Groundwater-affected soils have greater Ks in the subsoil due to their prismatic structure.

The unsaturated hydraulic conductivity, $K(Se)$ cm d^{-1} , can be determined as a function of the effective saturation, Se (-), with the combined Mualem-van Genuchten type analytical function and the bimodal retention function (Priesack and Durner, 2006),

$$K(Se) = K_s \left(\sum_{i=1}^k w_i Se_i \right)^\tau \left(\frac{\sum_{i=1}^k w_i \alpha_i [1 - (1 - Se_i^{1/m_i})^{m_i}]}{\sum_{i=1}^k w_i \alpha_i} \right)^2 \quad (7)$$

where Se is the effective saturation (-) with $(\theta - \theta_r)/(\theta_s - \theta_r)$, θ_s is saturated and θ_r is residual water content, respectively, α (cm^{-1}), n (-) and m (-), with $m = 1 - 1/n$, are empirical van Genuchten fitting parameters for both pore domains (index i), integer k denotes the

Fig. 6 Saturated hydraulic conductivity in vertical, K_{s_v} , and horizontal, K_{s_h} , direction of subsoil horizons (≤ 60 -cm depth) from representative soil types in Northern Germany under arable use (A) and grassland use (G); number of samples. Significant differences between K_{s_v} and K_{s_h} values are denoted as lowercase letters (ab), those between land use types by uppercase letters (AB), with a significance level of 0.05 (Horn et al., 2019).

Fig. 7 Unsaturated hydraulic conductivity, $K(Se)$ (cm d^{-1}), of a loamy sand with ρ_b between 1.15 g cm^{-3} and 1.25 g cm^{-3} at 5 cm depth, and ρ_b between 1.75 g cm^{-3} and 1.85 g cm^{-3} at 20 cm, 50 cm, and 80 cm depths, samples taken in vertical (ver) and horizontal (hor) directions (Beck-Broichsitter et al., 2020b).

modality of the model (i.e., $k = 2$ for bimodal), w_i is a weighting factor for the sub-curves of each pore domain ($0 < w_i < 1$ and $\sum w_i = 1$), and $\tau(-)$ is the tortuosity.

In Fig. 7, the results indicate direction-dependent differences in the $K(Se)$ values with depth, including the crumbly-structured soil at 5 cm depth and in the artificially compacted and therefore more platy structured soil at 20 cm, 50 cm, and 80 cm depths (Beck-Broichsitter et al., 2020c). The $K(Se)$ values were mostly related to the K_s values and predominantly to the existence of macropores (Beck-Broichsitter et al., 2020b), and the degree of saturation. Thus, the lower the saturation, the smaller is the share and area of conductive contact points per flow cross section resulting in a strongly decreasing unsaturated soil, while limiting the water flow in the soil matrix (Reszkowska et al., 2011).

Values of AR ranging between 4.5 and 1 in the nearly saturated range (Se ranging from 1.0 and 0.8) suggest an increased potential for lateral flow above a less permeable bedrock (Fig. 7). The $K(Se)$ values were also related to the mean K_s values with 554 cm d^{-1} in horizontal and 123 cm d^{-1} in vertical directions, and macropore volumes of 7.4% in vertical and 13.1% in horizontal directions. The predominantly horizontal-oriented pore network was created by plant roots and root fragments (Dohnal et al., 2012), and differently sized stones and rock fragments (Fig. 8).

The soil water diffusivity, $D(\theta)$ ($\text{cm}^2 \text{ d}^{-1}$), is the product of $K(\theta)$ and the differential water capacity, $dh/d\theta$ (i.e., slope of the water retention function), and the effective $D(\theta)$ values for the i -th pore size classes and can be calculated as,

$$D_i(\theta_i) = \int_{\theta_i^-}^{\theta_i^+} K(\theta_i) \frac{dh}{d\theta_i} d\theta \quad (8)$$

where $\theta^+(h^+)$ is the upper and $\theta^-(h^-)$ is the lower ranging between the i -th pore size classes: MaP ($h_1 \geq -10 \text{ hPa}$), wCP ($-10 > h_2 \geq -60 \text{ hPa}$), nCP ($-60 > h_3 \geq -300 \text{ hPa}$), MP ($-300 > h_4 \geq -15,000 \text{ hPa}$), and FP ($h_5 < -15,000 \text{ hPa}$).

Fig. 8 Unsaturated hydraulic conductivity, $K(Se)$ (cm d^{-1}), (left) and anisotropy ratio, AR (-), (right) of a sandy loamy BwC horizon of a Dystric Cambisol (AE/Bs/Bsw/BwC horizons) under forest use in 40 cm depth with ρ_b of 1.25 g cm^{-3} , samples taken in vertical (ver) and horizontal (hor) direction.

Fig. 9 D(θ)-weighted average anisotropy ratio, $AR_D(\theta)$, as a function of the volume fraction of macropores, MaP ($h_1 \geq -10$ hPa), and wide coarse pores, wCP ($-10 > h_2 \geq -60$ hPa), of a sandy loamy BwC horizon of a Dystric Cambisol (AE/Bs/Bsw/BwC horizons) under forest use in 40 cm depth with ρ_b of 1.25 g cm^{-3} , samples taken in vertical (ver) and horizontal (hor). The dashed lines indicate the confidence intervals of 95% of the relations between $AR_D(\theta)$ and the volume fraction of MaP and wCP, respectively.

A diffusivity-dependent effective weighted anisotropy ratio, $AR_{D(\theta)}$, per pore size class, i , can be calculated as,

$$AR_{D(\theta)} = D_i(\theta_i) \int_{\theta^+}^{\theta^-} \frac{1}{AR_i} d\theta \quad (9)$$

In Fig. 9, the D(θ)-weighted anisotropy ratios, $AR_D(\theta)$, indicate a positive linear relationship for the MaP (r^2 : 0.89–0.92) and wCP (r^2 : 0.49–0.61). The $AR_{D(\theta)}$ values strongly increase with the volume fraction of macropores and wide coarse pores, respectively (Beck-Broichsitter et al., 2020b, c).

The intensity-capacity concept, proposed by Horn et al. (2014), explores whether it is possible to predict intensity values (i.e., hydraulic conductivity, air permeability) with capacity parameters (i.e., bulk density, pore size distribution).

An intensity parameter like soil water diffusivity, $D(\theta)$, can be derived from the $K(\theta)$ function but it is less related to capacity parameters such as porosity and pore size distribution. This results because intensity parameters are also functions of pore continuity and connectivity and not directly of capacities derived from overall volumes (Horn et al., 2014).

Anisotropy of heterogenous structured materials analyzed by X-ray CT image analysis

Gas transport parameters such as air permeability and gas diffusivity can be effectively combined with porosity measured by X-ray computed tomography (CT) for multi-scale analyses (Piccoli et al., 2019). There is a direct link between soil physical properties and structure as obtained by imaging that can be used as the realistic boundary conditions for simulating processes and properties (Schlüter et al., 2018). Conventional soil mechanical methods can also be combined with X-ray CT to analyze the direction-dependent functional recovery of pores in the compacted subsoil (Beck-Broichsitter et al., 2020c).

Tensorial structural characteristics are needed to determine the degree of anisotropy and the preferred orientation (Doubé et al., 2010). The mean intercept length (MIL) tensor is the most used technique (Klatt et al., 2017) and the degree of the CT-based anisotropy (A_{CT}) can be calculated as,

$$A_{CT} = 1 - \frac{\text{Long axis eigenvalue}}{\text{Short axis eigenvalue}} \quad (10)$$

In Fig. 10, the sandy loamy BwC horizon of a Dystric Cambisol (AE/Bs/Bsw/BwC horizons) under forest use and formed by plant roots and rock fragments indicates a CT-based macroporosity (MaPCT) of $0.028 \text{ cm}^3 \text{ cm}^{-3}$ for vertical and $0.047 \text{ cm}^3 \text{ cm}^{-3}$ for horizontal oriented soil cores. The A_{CT} values are larger for the horizontal than for the vertical sampled soil core, while the predominant orientation of macropores is x-axis for the vertical and z-axis for the horizontal oriented soil core and therefore parallel to the sampling direction (90°).

(An-)Isotropy of mechanical properties and functions in structured soils

Stress strain processes in structured unsaturated soils

Mechanical stresses applied to a soil surface result in a 3-dimensional stress propagation and a coinciding induced strain. The extent to which these stresses are transmitted in soils depends on the internal soil strength and become more pronounced as soils become less aggregated, drier due to more negative matric potential, or abundant in organic carbon content. Furthermore, stress transmission depends on texture, clay mineralogy, and composition of organic acids.

Generally, mechanical processes across 3 dimensions in soils are described by the stress-strain equation (i.e., Hartge and Horn, 2016) as,

Fig. 10 X-ray CT image of the macropore volume ($\text{MaP}_{\text{CT}}: d > 1.134 \text{ pixel}$) of a sampled soil core using Fiji/ImageJ (Koestel, 2018) as ratio between phase volume (voxel) and bulk volume (voxel) of the region of interest, ROI.

$$\begin{bmatrix} \sigma_x(\vec{x}, t) & \tau_{xy}(\vec{x}, t) & \tau_{xz}(\vec{x}, t) \\ \tau_{xy}(\vec{x}, t) & \sigma_y(\vec{x}, t) & \tau_{yz}(\vec{x}, t) \\ \tau_{xz}(\vec{x}, t) & \tau_{yz}(\vec{x}, t) & \sigma_z(\vec{x}, t) \end{bmatrix} = f \begin{bmatrix} \varepsilon_x(\vec{x}, t) & \varepsilon_{xy}(\vec{x}, t) & \varepsilon_{xz}(\vec{x}, t) \\ \varepsilon_{xy}(\vec{x}, t) & \varepsilon_y(\vec{x}, t) & \varepsilon_{yz}(\vec{x}, t) \\ \varepsilon_{xz}(\vec{x}, t) & \varepsilon_{yz}(\vec{x}, t) & \varepsilon_z(\vec{x}, t) \end{bmatrix} \quad (11)$$

where f defines the soil specific material properties. In the case of a linear-elastic isotropic material, the tensor notation reads as,

$$\begin{bmatrix} \sigma_x & \tau_{xy} & \tau_{xz} \\ \tau_{xy} & \sigma_y & \tau_{yz} \\ \tau_{xz} & \tau_{yz} & \sigma_z \end{bmatrix} = \frac{E}{1 + \nu} \begin{bmatrix} \varepsilon_x - \varepsilon_m & \varepsilon_{xy} & \varepsilon_{xz} \\ \varepsilon_{xy} & \varepsilon_y - \varepsilon_m & \varepsilon_{yz} \\ \varepsilon_{xz} & \varepsilon_{yz} & \varepsilon_z - \varepsilon_m \end{bmatrix} + \frac{E}{3 \cdot (1 - 2 \cdot \nu)} \cdot \begin{bmatrix} \varepsilon_m & 0 & 0 \\ 0 & \varepsilon_m & 0 \\ 0 & 0 & \varepsilon_m \end{bmatrix} \quad (12)$$

where E is $\Delta\sigma/\Delta\varepsilon$ (Young's modulus or modulus of elasticity) and ν is Poisson's ratio.

The first tensor, ε_m , describes the volume constant shear deformation and the second tensor the volumetric strain with the mean volume strain ε_m defined as (Hartge and Horn, 2016),

$$\varepsilon_m = \frac{1}{3} \cdot (\varepsilon_x + \varepsilon_y + \varepsilon_z) = \frac{1}{3} \cdot \varepsilon_{\text{vol}} \quad (13)$$

For example, Riggert et al. (2016) documented the variation in stress transmission in structured unsaturated soils under conventional, conservation, and forestry management by determination of the stress state components as well as the tensorial varying volumetric displacements as a function of the applied stresses. The proportions of the major and minor stresses as well as the mean normal stress (MNS) or octahedral shear stress (OCTSS) depend on soil aggregation like coherent, prismatic, polyhedral, subangular blocky, crumbly, or platy structures.

The internal soil strength (precompression stress or soil rigidity) quantifies the consequences of mechanical, hydraulic, chemical, or biological stresses on the tensorial components of the stress strain ratio (Horn and Blum, 2020). While stress transmission in incompressible water is completely isotropic, soils behavior ranges from mostly vertically anisotropic if they are very weak (i.e., moist, with mostly coherent structure and fine textured) to an increased proportion of horizontal deformation in stronger aggregated soils with subangular blocky, crumbly structure or soils with platy structure. In this case the total affected stressed soil volume is reduced. The vertical anisotropy fades off and finally reaches isotropy. Coinciding with this, the deviator stress at rest k ($\sigma_1^* k = \sigma_3$) varies between 0.2 and > 1 depending on the internal soil strength.

Fröhlich (1934) defined these strength dependent changes with the concentration factor, which for substrates ranged between 3 for very hard (isotropic deformation behavior) up to 9 for weak and/or wet material conditions. However, because of limited soil rigidity, a precompression stress dependency needs to be incorporated which affects the volumetric stress strain, too (Horn and Blum, 2020). Exceeding the internal soil strength causes an increase in the concentration factor, a more intense vertical soil deformation and a coinciding increased vertical anisotropy.

Quantification of structure dependent changes by tensorial stress strain and shear stress components

Based on the vectorial composition of the strength properties and functions, the direction dependent changes in the shear resistance parameters (angle of internal friction, ϕ , and cohesion, c) and precompression stress (P_c), can also have isotropy or anisotropy patterns. For instance, stress induced breakage of a platy structure is highly direction dependent, with the intensity of the stress application beyond the rigidity limits differing in vertical and horizontal directions (Fazekas and Horn, 2005). From shear

Fig. 11 Angle of internal friction, ϕ , and cohesion, c , for a Haplic Luvisol derived from glacial Weichselian till (site CIS2) as a function of stress applied and sampling direction. The matric potential was -60 hPa, ϕ_{sv} and ϕ_{sh} denote: structure-related angle of the friction of the samples taken vertically (v) and horizontally (h), while c_{sv} and c_{sh} define the corresponding cohesion values. The factors s and t define the stress ranges applied: s is stresses smaller than the precompression stress, t is stress within the virgin compression stress (Dörner and Horn, 2009).

measurements and stress strain analyses the directional dependence can be quantified, with the applied stresses possibly coinciding with a new anisotropic platy structure formation in deeper soil depths.

Furthermore, P_c values strongly depend on soil aggregation and show very distinct differences for soil samples collected in vertical vs. horizontal directions. For a platy structure, the ratios of horizontal to vertical P_c values (AR_{P_c}) are greater than 1 due to their formation by the complex stresses of wheeling. The latter was observed in a platy structure plow pan in a loess derived Luvisol down to 60 cm depth (Fazekas and Horn, 2005). On the hand, less anthropogenically affected soils with a crumblier structure show AR_{P_c} values <1 . Likewise, the ratio of the horizontal to vertical shear parameters for c (A_c) and ϕ (A_ϕ) follow similar trends in disturbed compared with well-managed soils, being >1 for a platy structure but changing to <1 for sites under conservation tillage that improved soil structure (i.e., Fazekas and Horn, 2005). These changes underline the tensorial effects and reactions on soil strength due to its limited rigidity, which can be derived from the stress dependent changes in these ratios. For a coherent structure, ϕ and c values are mostly identical, while a prismatic structure indicates slightly greater ϕ and c values in vertical than horizontal direction, while platy structured soils show an opposite trend (i.e., Dörner and Horn, 2009).

In Fig. 11, the subangular blocky-structured Ap horizon of a Luvisol, derived from glacial till, shows values for the shear resistance lower than the P_c , while the sampling direction indicates no differences in ϕ values, but greater c for samples taken vertically (Dörner and Horn, 2009).

Consequences of the strength anisotropy for land sliding processes

In Fig. 12, the direction dependent shear parameters in aggregated soils also modify the bearing capacity induced volumetric strain behavior as it depends directly on the ϕ and the c (Hartge and Horn, 2016). The prediction of the tensile failure pattern (extension, Rankine's active pressure distribution) requires the application of those values determined for vertically sampled soils, but the

Fig. 12 Schematic description of the bearing capacity induced volumetric strain behavior (Hartge and Horn, 2016).

opposite is true for the Rankine's passive pressure distribution. Horizontally sampled soil parameters are required to define the deformation and failure patterns as the exit angle, which reads as $45^\circ - \varphi/2$. Well-structured soils have a flatter exit angle of the laterally moved soil volume (passive movement) compared with weaker aggregated soils (Hartge and Horn, 2016).

Conclusion

Soil structure not only has a significant influence on soil stability (P_c) and the shear parameters φ and c but also on the vertical or horizontal flow of water. Soil deformation ($P_c < \text{stress}$) due to mechanical loads can lead to a distinct horizontal anisotropy of the soil pore system because of anthropogenic induced plate structure formation. This promotes surface runoff and thus increased soil erosion and may reduce biomass productivity. Shear parameters are thus tensors which depend on soil aggregation and other internal properties.

Direction-dependent differences in the soil water diffusivity as a link between intensity and capacity parameters are strongly related to the pore size distribution. The greatest impacts are from macropores to narrow coarse pores. Thus, by weighting the anisotropy ratio, $AR_{D(\theta)}$, with the soil water diffusivity, both the capacity and the intensity parameters were combined. Small-scale direction-dependent differences in the soil hydraulic capacity and intensity parameter will be used for model-based upscaling for better understanding of water flow at the catchment scale.

However, additional research is needed to extend these results to further soil profiles information under various tillage systems and soil properties, and to finally document these interactions more completely. In conclusion, mechanical and hydrological soil functions are tensors that depend on the soil structure and the stresses applied in comparison with soil mechanical stability.

Abstract

Macropores are large pores in soil created by both physical processes (e.g., swell-shrink) and biological agents (e.g., plant roots and soil fauna). Macropores have profound impacts on various critical soil ecosystem services/disservices (e.g., flood prevention, contaminant leaching). In this article, we first discuss the nature of macropores and explain why they are important. We then discuss how the “architecture” of macropore networks affects water flow, before outlining some approaches that are commonly used to model water flow through soils containing macropores. We conclude with some suggestions for future research that may prove fruitful.

Glossary

Macropores Large diameter structural pores in soil created either by physical (i.e., swell/shrink) or biological (root turnover, faunal activity) processes.

Macropore flow The preferential channeling of water flowing through soils in macropores due to an extreme contrast in permeability with surrounding matrix pores.

Non-equilibrium flow Refers to the fact that single representative values of pressure potential and/or solute concentration cannot be identified for a soil volume through which water is flowing. This is a diagnostic feature of all preferential flow processes, including macropore flow.

Percolating pore space That part of the pore space which is connected to both the upper and lower surfaces of a considered soil volume.

Percolation threshold A critical (minimum) value of soil porosity needed for the pore space to become long-range connected. Above the threshold, the pore space is said to percolate.

Preferential flow Flowing water is channeled through a limited part of the soil pore space.

Key points

- Macropores are large diameter structural pores in soil created by either physical (e.g., swell-shrink) or biological (e.g., faunal activity) processes.
- Macropores allow fast “preferential” channeling of water through soils due to the extreme contrast in permeability with surrounding matrix pores.
- Macropores have both detrimental environmental impacts (e.g., enhancement of contaminant leaching risks) but also significant beneficial ecosystem services (e.g., reduction of runoff and flooding risks).

Introduction

Soil macropores and the occurrence of macropore flow were recognized as long ago as the late 19th century. From measurements of drainage flow and the leaching of agrochemicals at Rothamsted in the U.K., Lawes et al. (1882) observed that . . . “in a heavy soil, channel drainage will in most cases precede general drainage, a portion of the water escaping by the open channels before the body of the soil has become saturated; this will especially be the case if the rain fell rapidly, and water accumulates on the surface.” They further concluded that “... the drainage water from a soil may thus be of two kinds: it may consist (1) of rain-water which has passed, with but little alteration in composition, down the open channels of the soil; or (2) of the water discharged from the pores of a saturated soil.” However, this accurate, yet qualitative,

description of rapid non-equilibrium water flow through soils containing macropores was largely ignored during the ensuing century. Instead, quantitative approaches introduced by Edgar Buckingham and Lorenzo Richards in the early 1900's laid much of the foundation of soil water physics in the decades that followed. This classical theory of soil water flow is based on an underlying assumption of homogeneity, that unique values of water potential, water content and hydraulic conductivity can adequately characterize a soil volume (i.e., that a so-called representative elementary volume—REV—exists for these properties). Solute transport theory developed along conceptually similar lines, with the advection-dispersion equation (ADE) becoming extensively used from the middle of the 20th century. The significance of macropores was re-discovered in the 1970s and early 1980s, as new experimental observations of their effects on soil water flow and solute leaching began to challenge these established paradigms (Thomas and Phillips, 1979; Beven and Germann, 1982). Research into all aspects of macropore flow has dramatically intensified during the last 40 years (Jarvis et al., 2016; Nimmo, 2020).

What are macropores?

Macropores are comparatively large pores in soil that develop as a consequence of various mechanisms of soil structure formation, including physical processes such as wetting and drying and freeze-thaw cycles, which cause soil cracking, and the actions of biological agents, especially the growth and decay of plant roots and the activity of soil fauna (Meurer et al., 2020). In most soils, macroporosity will tend to decrease with depth in parallel with a decline in the intensity of these structure-forming processes. Below the plant root zone, macroporosity derived from biological activity and soil wetting and drying cycles will usually be minimal, although fissures of geological origin may be present in the underlying soil parent material. Macropores tend to be biological “hot-spots,” especially in undisturbed soils (e.g., untilled soils or subsoils in arable land), supporting a significantly greater biomass, activity and functional diversity of the microbial community. This is because surface-vented macropores efficiently supply nutrients and oxygen to roots and microorganisms and because living plant roots often grow preferentially in or close to macropores, which provides a supply of carbon from root exudation and turnover. Compared with the bulk soil, the interfaces between subsoil macropores and bulk soil are often characterized by coatings and linings that are enriched in either clay or organic carbon, or both. These internal interfaces in soil may be more impermeable and/or hydrophobic than the bulk soil and also more chemically reactive (see references in Jarvis, 2007).

What are macropore and preferential flows?

The presence of macropores can result in extreme contrasts in permeability at the pore-scale, which can lead to large spatial variations in pore water velocities and solute displacement as water infiltrates the soil during precipitation events. Water flow in macropores is one of three processes which can result in so-called preferential flow in soil, such that flowing water is channeled through only a limited fraction of the total pore space. A convergence of flow toward a limited number of flow paths leads to non-equilibrium in pressure potential transverse to the flow direction, which is a diagnostic feature of preferential flow (Beven and Germann, 1982). These non-equilibrium hydraulic conditions can be exemplified by non-monotonic wetting patterns recorded in plot experiments in the field. In these situations, soil water monitoring devices (e.g., tensiometers or time-domain reflectometry probes) located deep in the soil in contact with water-conducting macropores show a faster response to precipitation than probes installed at shallower depths, but not in contact with macropores (see studies cited in Jarvis et al., 2016). It is not straightforward to identify a specific minimum pore diameter that enables non-equilibrium flow conditions to develop, not least because pore continuity (or connectivity) also plays an important role (see “Macropore network characteristics and macropore flow”). Nevertheless, evidence from the use of a variety of experimental methods suggests that pores larger than ca. 0.3–0.6 mm in diameter will generally allow preferential flow (Jarvis, 2007).

Preferential flow can also occur in the form of unstable “finger flow” in homogeneous coarse-textured or water repellent soils. The third preferential flow process, often termed funnel flow (or simply heterogeneous flow) occurs as a consequence of macroscopic spatial variations in hydraulic properties in heterogeneous soils. We will not further discuss heterogeneous flow in this chapter as, in principle, it can be dealt with by extending applications of the Richardson-Richards and ADE equations to two or three spatial dimensions. In contrast, macropore flow is a pore-scale phenomenon (Jarvis, 2007; Jarvis et al., 2016) that invalidates the use of continuum model approaches like the Richardson-Richards' equation for water flow and the ADE for solute transport, as a REV cannot be identified at a given depth in the soil for the key state variables (i.e., water content, matric potential and solute concentration).

It should be noted that the three types of preferential flow may occur simultaneously in some soil types (Jarvis et al., 2016). However, in general, macropore flow is probably the most important of the three processes, especially in finer-textured soils where they provide a sufficient contrast in permeability with the surrounding (bulk or matrix) pore space. Furthermore, macropores are ubiquitous in all soils, they are often continuous along large parts of the soil profile and pore water flow velocities in macropores can be very large. Data collated from the literature suggests that macropore flow velocities in soils are typically between 0.1 and 10 m d⁻¹, with a median value of 3.5 m d⁻¹ (Nimmo, 2007; Nimmo et al., 2021). A word of caution is appropriate here, as many of these experiments were conducted with precipitation intensities and amounts that are uncommon under natural conditions in most

climates (see [Jarvis, 2007](#)). Flow velocities in macropores are sensitive to water input rates at the soil surface, so that values toward the lower end of this reported range would be more likely for rainfall events of more typical intensities.

Soil physics theory suggests that local pressures close to atmospheric pressure are required to generate water flow into macropores (see references in [Jarvis, 2007](#)). These near-saturation conditions will occur more frequently in soil characterized by a limited matrix permeability, for example, in clay soils or soils compacted by vehicle traffic. Water repellency, which often develops during the drying of uncultivated soils under natural vegetation, can also strongly enhance the generation of macropore flow ([Jarvis, 2007](#); [Jarvis et al., 2016](#)) as it reduces the infiltration capacity of the soil matrix and the required water potentials can then be quickly reached, even for rainfall events of low intensity. Near-saturated conditions need only occur locally to generate macropore flow. As noted above, preferential flow is a non-equilibrium process, so that once it has been initiated, water flowing in macropores may rapidly “by-pass” the surrounding dry soil matrix, providing the supply rate to the macropores is larger than the imbibition rate into the matrix. In this respect, the distinct physico-chemical properties of macropore/matrix interfaces may drastically reduce uptake rates of water and solutes into the matrix, which enhances the strength of macropore flow and thus also the risk of leaching of contaminants (see studies cited by [Jarvis, 2007](#)).

Irrespective of size, water flow in all soil pores is governed by the same fundamental momentum balance between driving forces (gravity and matric potential gradients), inertial forces, and the resistances to flow arising from friction between water and the solid surfaces and within the water itself. Although these same forces operate on water in all pores, the balance between them differs for water flowing rapidly in macropores compared with slower flowing water in much smaller matrix pores. Firstly, gravity dominates the driving force for water flow in macropores as significant matric potential gradients are highly unlikely to develop. Furthermore, the pore water velocities in macropores may become so large that the acceleration terms in the momentum balance may not be negligible and the flow is no longer laminar (see studies cited in [Jarvis, 2007](#)). Such flow conditions violate assumptions implicit in the Richardson-Richards equation describing creep flow.

Why is macropore flow important?

Water flow in macropores is associated with potentially significant ecosystem disservices. For example, on strongly sloping land, it is implicated in a loss of slope stability, landslides and gully erosion (e.g., [Hencher, 2010](#); [Wilson et al., 2013](#)). Fast non-equilibrium water flow through macropores can also seriously impact the quality of groundwater by short-circuiting the chemical and biological capacity of the soil in the unsaturated zone to retain and degrade potential contaminants (e.g., [Jarvis, 2007](#); [Clothier et al., 2008](#)). In this respect, macropore flow is an especially critical process for otherwise relatively immobile or quickly degrading solutes that are foreign to the soil and whose effects on aquatic ecosystems or human health are significant at small leached fractions (e.g., pesticides; [Jarvis, 2007](#)). In contrast, the leaching of relatively mobile solutes that are also indigenous to the soil (e.g., nitrate) will be less affected by macropore flow. In a similar way, macropore flow can also impact surface water quality via discharges from field drainage systems. However, in this context, it should be remembered that an absence of macropores would severely impair drainage, leading to surface runoff, which in most cases would result in significantly greater adverse impacts on surface water quality.

Macropores also provide significant beneficial ecosystem services related to soil hydrology. In particular, macropores open to the soil surface enhance infiltration capacity and drainage rates ([Beven and Germann, 1982](#)) thereby minimizing the risks of severe waterlogging, surface runoff and soil erosion. In terms of impacts on the soil water balance, macropores that function as non-equilibrium flow pathways through the unsaturated zone will increase recharge to groundwater, while correspondingly reducing soil water contents and evapotranspiration. However, although they play a critical role in partitioning precipitation at the soil surface between infiltration and surface runoff, the impact of macropores on the re-distribution of infiltrated water in soil and recharge to groundwater is likely to be quite limited in most cases ([Or, 2019](#)), certainly in comparison with their impact on the risk of contaminant leaching ([Jarvis, 1998](#)).

Macropore network characteristics and macropore flow

[Allaire et al. \(2009\)](#) and [Jarvis et al. \(2016\)](#) comprehensively reviewed the wide variety of experimental methods that have been used to study the properties of macropores and macropore flow in both the laboratory and in the field, so only a brief summary is provided here. Common approaches to studying macropore flow in the field include the quantification of dye staining patterns following infiltration as well as the use of routine soil physical techniques to monitor the time-course of responses of either soil water potentials or water contents to precipitation events. In the laboratory, the extent of preferential flow is commonly assessed by analyzing breakthrough curves for non-reactive tracer compounds that represent travel-time distributions under steady water flow. Macropore flow has also been monitored at intermediate scales on large outdoor monoliths or lysimeters under more field-like (i.e., transient) conditions.

The morphological properties of the macropores themselves are clearly also of great interest. Although they are difficult to characterize in the field, some methods have been developed based on soil excavation following the infiltration of hard-setting materials ([Allaire et al., 2009](#)). However, these methods are not widely employed as they are laborious and because they only reveal very large macropores. In the laboratory, early studies used staining approaches in combination with thin-sectioning techniques to

quantify the properties of soil macropores. In more recent years, this approach has been largely supplanted by X-ray scanning technologies as these enable the quantification of a range of geometrical and topological properties of soil macropores in 3D and for larger soil samples (see Fig. 1). The use of X-ray scanning has, for example, revealed that soil macroporosity is generally comprised of a number of individual networks or “clusters” separated from one another by smaller matrix pores, with each network being characterized by multiple pathways of variable thickness, including bottleneck constrictions and “dead-ends.”

Recent studies making use of X-ray tomography have confirmed expectations that some of the key concepts in a mathematical theory of connectivity termed “percolation theory” should be applicable to soil macropore networks (Jarvis et al., 2017a; Lucas et al., 2020; Koestel et al., 2020). In particular, these studies show that soils appear to follow one of the underlying premises of percolation theory, in that the long-range connectivity of macroporosity is achieved at a critical value termed the percolation threshold. For soils with macroporositities above this threshold value, individual clusters merge into one “giant” long-range connected cluster. The dependence of pore connectivity on porosity means that more sparsely distributed larger diameter macropores will generally be less well connected than smaller diameter macropores or mesopores that are usually characterized by larger pore volumes. In this respect, Koestel et al. (2020) showed that dense networks of pores between 80 and 250 μm in diameter were especially important in linking together much larger macropores that would otherwise be disconnected.

Experimental studies that combined imaging methods to quantify the properties of macropore networks with experiments to quantify water flow and solute transport on the same samples have led to new insights into how the properties of macropore networks influence macropore flow. For example, Larsbo et al. (2014) related macropore network characteristics quantified by X-ray to the strength of macropore flow determined from steady-state tracer breakthrough experiments under near-saturated flow conditions for 18 topsoil columns sampled from four arable sites, all but two of which had percolating macroporosity. They found that for soils with small macroporosity, the macropore saturation and the diameter of the largest water-filled pore was larger, which led to stronger preferential flow (Fig. 2). Similar experimental results were reported by Katuwal et al. (2015) and by Larsbo et al. (2016). At their field site, Larsbo et al. (2016) reported that preferential flow was significantly weaker for soils rich in organic carbon that were characterized by dense well-connected networks of pores 200–600 μm in diameter.

These findings can be explained by a conceptual model based on percolation concepts (Larsbo et al., 2014), such that the degree of preferential flow will increase as macroporosity decreases, providing that macroporositities are larger than the percolation threshold where long-range connectivity breaks down (see schematic illustration in Fig. 3). Below this threshold, the macropore clusters are disconnected and many will not be open to the water supply at the soil surface. Water flowing into disconnected macropore clusters will accumulate at dead-ends or “bottlenecks,” resulting in saturation and the re-distribution of water to the surrounding matrix pores, a process termed internal catchment. The development of local near-saturated conditions in the soil matrix adjacent to another macropore cluster would then be required to trigger further macropore flow. Thus, both experimental

Fig. 1 X-ray images of macropore networks (pore space $>500 \mu\text{m}$ in diameter) in two of the samples included in the study by Koestel et al. (2020). Cylindrical aluminum cores (65 mm in diameter, 60 mm in height) were taken from a soil pit in an agricultural field at Ås, $\sim 30 \text{ km}$ south of Oslo, Norway, at depths of 4–10 cm in the topsoil (a) and 90–96 cm in the subsoil (b). The imaged volumes correspond to a cross-section of $4 \times 4 \text{ cm}$ and a height of 5.2 cm. The original image resolution was $80 \mu\text{m}$.

Fig. 2 Relationships between the 5% tracer arrival time and (a) the degree of saturation in the X-ray imaged pore space and (b) the diameter of the largest water-filled pore, for four soils at five different steady water flow rates varying between 2 and 12 mm h⁻¹. Dashed lines represent linear regression lines for each flow rate. All regression slopes were significantly (p value < 0.05) different from zero. The 5% tracer arrival time is a non-parametric measure of the strength of preferential flow, which is defined as the (normalized) time at which 5% of an applied tracer pulse has leached from the bottom of the core. Figure re-drawn from Larsbo, M, Koestel, J, Jarvis, N (2014) Relations between macropore network characteristics and the degree of preferential solute transport *Hydrology and Earth System Sciences* 18: 5255–5269.

Fig. 3 Schematic illustration of the relationship between pore connectivity, water-filled flow pathways, macroscopic flow capacity (saturated hydraulic conductivity) and the strength of preferential transport. Two classes of soil pore are represented in the figures with contrasting porosity and diameter: a dense network of mesopores and six larger diameter macropores. Conducting water-filled (backbone) pores are indicated in light-blue, empty or dead-end pores in dark brown (a) a dense well-connected percolating pore network (a single pore cluster) with a uniformly high (macroscopic) saturated hydraulic conductivity denoted by the dark shading. The connected mesopore network has a sufficiently large flow capacity to conduct all the incoming water, so the degree of preferential flow is consequently low (b) this network was created from the first network by removing some of the mesopores to create six isolated pore clusters. The flow capacity of the mesopore network is now severely impaired, because it is poorly connected at the sample scale. The water flow is therefore now diverted to a cluster containing a single macropore that is continuous through the sample. The sample now exhibits a high degree of preferential flow. At the macroscopic scale, this is reflected in a continuous high conductivity pathway through the sample (dark shading) surrounded by a low conductivity matrix (light shading) (c) after removing the single continuous macropore, sample-scale continuity breaks down, which reduces the strength of preferential flow. Saturated hydraulic conductivity is also now uniformly low. Figure adapted from Larsbo, M, Koestel, J, Jarvis, N (2014) Relations between macropore network characteristics and the degree of preferential solute transport. *Hydrology and Earth System Sciences* 18: 5255–5269.

and theoretical studies suggest that preferential flow may occur through soil containing disconnected macropore networks, although it does so to a more limited extent (see studies cited in Jarvis et al., 2016). A lack of connected macroporosity can also lead to soil waterlogging, surface runoff and erosion during especially heavy rainstorms.

Precipitation rates will usually be much smaller than the soil saturated hydraulic conductivity in soils with percolating macropore networks. In such cases, the water flow in macropores will be unsaturated and its geometrical configuration will vary with pore network characteristics, input rates and the degree of saturation (e.g., Jarvis, 2007; Jarvis et al., 2016, 2017b; Nimmo, 2020). At low

macropore saturations, “film” or “rivulet” flow may take place along macropore surfaces. As water inputs and the degree of saturation increase, capillary “bridging” across the narrowest sections of macropores and “pulse” flow may occur (Jarvis, 2007). Bottlenecks along the flow pathways, together with air entrapment, mean that macropores usually remain unsaturated during water flow even under extremely high input rates or even saturation of the soil surface (Beven and Germann, 1982; Jarvis, 2007; Nimmo, 2020). The contrasting flow configurations that develop in response to variations in input rates at the surface have consequences for pore water velocities in macropores and the strength of preferential flow. This is briefly discussed in section “Modeling macropore flow and transport” in relation to the widely-used kinematic wave model, where the kinematic exponent should reflect differences in flow configurations in soil macropores.

Modeling macropore flow and transport

A wide variety of modeling approaches have been developed that can account for macropore flow. We do not attempt to provide a comprehensive review here, referring the reader instead to Šimůnek et al. (2003), Gerke (2006) and Jarvis et al. (2016). Instead, we focus on a few of the more widely-used concepts, highlighting their strengths and limitations. Ideally, water flow in soil macropores would be modeled directly at the pore-scale using the fundamental Navier-Stokes equations of flow, or approximations of them. In this way, the impacts of macropore flow at larger scales (e.g., soil profiles) would emerge as a consequence of the characteristics of the macropore network and the imposed boundary conditions. Recent advances in X-ray imaging technologies and computational methods have enabled some studies of this kind (e.g., Scheibe et al., 2015). However, numerical solutions of the pore-scale flow equations are computationally extremely demanding and the sample sizes used for X-ray imaging are limited by the size and resolution of the equipment. As a result, this kind of approach has so far been limited to simulation domains that are too small to be of practical interest and almost certainly much smaller than would constitute a REV for macropore flow in structured soils (Koestel et al., 2020).

At the opposite extreme of model complexity, steady-state pore water flow velocities and travel times in macropores have been estimated from various analytical solutions of the Navier-Stokes flow equations that can be derived for highly idealized macropore geometries and flow configurations, such as free water films of constant width or fully saturated flow through cylindrical pores (i.e., the Hagen-Poiseuille equation). These models can all be encapsulated in a single generalized equation by making use of the concept of an effective soil hydraulic radius, R_h (m), which is defined as the ratio between the macropore water content θ_{mac} ($\text{m}^3 \text{m}^{-3}$) and the wetted specific surface area in soil ($\text{m}^2 \text{m}^{-3}$). In this approach, the rate of gravity-driven laminar water flow, q_{mac} (m s^{-1}), through a macroscopically homogeneous macropore “domain” with only a limited range of macropore diameters, can be expressed as:

$$q_{mac} = \left(\frac{g}{G \mu \tau} \right) \theta_{mac} R_h^2 \quad (1)$$

where g is the acceleration due to gravity ($= 9.8 \text{ m s}^{-2}$), G is a flow geometry factor (dimensionless) varying between 2 for cylindrical geometry and 3 for planar geometry, μ is the kinematic viscosity ($= 10^{-6} \text{ m}^2 \text{s}^{-1}$) and τ (dimensionless) is the flow path tortuosity. Putting appropriate values for R_h in Eq. (1) leads to the special cases of this general model that are applicable to idealized flow geometries. For example, by definition, R_h takes values of $d/4$, $d/2$, and d for saturated cylindrical channels, saturated slits and free planar films, where d is the channel diameter, slit width, or film width. However, great care should be exercised in using simple models based on Eq. (1), as the geometrical configuration of water flowing through macropores in natural soils may not reflect the assumptions underlying the chosen form of the model. For example, the Hagen-Poiseuille equation, which is derived for saturated water flow through a cylindrical pore, is not appropriate to describe macropore flow in natural soils characterized by complex and irregular inter-connected pore networks, through which the flow is usually unsaturated (Jarvis et al., 2016, 2017a; see section “Macropore network characteristics and macropore flow”).

For natural soils that are subjected to highly intermittent precipitation regimes in the field, both macropore water contents and flow rates inevitably vary with time (i.e., transient conditions prevail). The so-called kinematic wave equation has been proposed as a flexible and relatively parsimonious approach to modeling variably-saturated water flow in macropores (Germann, 1985). Jarvis et al. (2017b) showed that an easy-to-use form of the kinematic equation can be derived from Eq. (1) by (i.) assuming a power law relationship between the wetted surface area and water content in the macropores, and (ii.) replacing the difficult-to-estimate parameters that explicitly characterize the geometry of flow by the saturated hydraulic conductivity of the macropores, $K_{s(mac)}$, which can be more easily measured. This leads to (Jarvis et al., 2017b):

$$q_{mac} = K_{s(mac)} \left(\frac{\theta_{mac}}{\phi_{mac}} \right)^\alpha \quad (2)$$

where ϕ_{mac} is the conducting macroporosity and α is the kinematic exponent, which reflects the geometrical configuration of water flowing through the macropores (Jarvis et al., 2017b). The model is completed by combining Eq. (2) with a continuity equation:

$$\frac{\partial \theta_{mac}}{\partial t} = -\frac{\partial q_{mac}}{\partial z} \quad (3)$$

where t is time and z is height. Eqs. (2) and (3) can be solved either analytically for relatively simple initial and boundary conditions (Germann, 1985) or numerically for complex, irregular conditions (Larsbo et al., 2005). Making use of concepts from percolation theory, the conducting macroporosity ϕ_{mac} in Eq. (2) can be identified with the “backbone” of the percolating clusters (i.e., the macropore network excluding dead-end macropores). To maintain strict physical realism, the kinematic exponent should lie between 1 and 3, as this ensures that pore water velocities in macropores increase with increases in flow rate, saturation and wetted surface area (Jarvis et al., 2017b). A value for the kinematic exponent of 1 implies that the velocity of water flow in macropores will be at a maximum independent of input rate and macropore water content (Nimmo, 2007; Jarvis et al., 2017b). At the other extreme (i.e., $\alpha = 3$), flow velocities are at a minimum and wetted surface areas are constant irrespective of θ_{mac} (e.g., Jarvis et al., 2017b).

Combining a macropore flow model with descriptions of flow and transport in the soil matrix significantly enhances the potential range of applications of the model to help resolve practical questions in management, policy and decision-making. Dual-permeability models (Šimůnek et al., 2003; Gerke, 2006) are commonly used for such purposes. These models treat the soil macroporosity and matrix as two interacting flow regions without any explicit consideration of the geometry and topology of flow paths in either domain. Classical theory (i.e., the Richardson-Richards equation and ADE) is generally adopted to describe flow and transport in the soil matrix. Different approaches have been used to calculate water flow in the macropore domain. In some models, the Richardson-Richards equation is used to calculate water flow in both flow domains. One potential problem with this is that some of the underlying assumptions (e.g., that the viscous resistances to flow are dominant and flow is laminar) may not be appropriate for the flow of water in macropores (Jarvis, 2007). A parsimonious alternative approach is to employ the kinematic wave equation to model flow in the macropore region (Larsbo et al., 2005). As with all models, dual-permeability approaches suffer from some theoretical weaknesses and limitations (Vogel, 2019). One important limitation is that any macroporosity present is implicitly assumed to be fully connected, which means that internal catchment due to dead-end macropores can only be simulated at one depth in the soil profile. Another potentially key question that has not been resolved, and which is common to all continuum model approaches, is whether a REV can be identified for macropores (Beven and Germann, 1982; Koestel et al., 2020). At present, the experimental evidence is supportive for topsoil characterized by relatively dense macropore networks (Fig. 2; Larsbo et al., 2014), whereas this condition may not be met for sparsely distributed macropores in subsoil (Fig. 1; Koestel et al., 2020). The approximate first-order treatment of mass transfer between the two distinct pore regions also introduces model error in terms of an apparent time-dependence of the mass transfer coefficient. Another important issue in applying these models is that some of the parameters, especially those controlling exchange of water and solutes between the two flow regions, are difficult or even impossible to measure, and must therefore be derived by model calibration. This emphasizes the importance of adopting suitable methods to deal with model parameter and prediction uncertainties. Nevertheless, despite both theoretical and practical limitations, repeated calibration and testing of dual-permeability models against data from laboratory columns, lysimeters and field plots (Köhne et al., 2009a,b) has generated sufficient confidence in their reliability that they are now commonly used as tools by practitioners and stakeholders for various management purposes.

Conclusions and outlook

Macropore flow has been extensively studied since the early 1980s, but its regulation by pore system characteristics remained poorly understood for many years. This is because until recently the soil has been a “black box,” with the nature of its pore system unseen and therefore impossible to directly quantify. In more recent years, advances in non-destructive X-ray scanning techniques and image analysis tools have allowed researchers to directly observe and quantify the complex multi-scale geometry of the soil pore system, and the water flowing within it, at a steadily improving resolution. This has led to a better understanding of how pore network properties control non-equilibrium macropore flow at the pore to core scale. In this respect, concepts borrowed from percolation theory have also proven useful to interpret experimental results, in particular to highlight the role and significance of network connectivity. However, in the context of macropores and macropore flow, percolation theory has so far mostly remained an explanatory rather than a predictive model. There should therefore be considerable scope to make more use of concepts from percolation theory in macropore flow models. We also expect to see an increasing use of non-invasive imaging techniques to directly test and parameterize macropore flow models. This will lead to an improved understanding of the process itself and more reliable model predictions in practical applications with less need to resort to calibration.

For some management purposes (e.g., as decision-support tools for pesticide registration), model simulations at the soil profile scale are sufficient, which means that important questions related to parameterization and prediction uncertainty are manageable. However, macropore flow also has important consequences for hydrological processes and water quality at much larger scales (e.g., catchments, regions) and in such cases model end-users need to “bridge” across this scale gap for management and decision-making (Vogel, 2019; Nimmo et al., 2021). Hydropedological approaches based on the mapped spatial distribution of representative soil-hydrological types in combination with pedotransfer functions and rules may offer a pragmatic and reliable way to employ soil profile-scale models at the landscape scale (Lin, 2003; Or, 2019; Vogel, 2019).

Macropore networks are dynamic, with changes induced by climate and land use and mediated by physical and biological processes operating at time-scales ranging from seconds to decades (e.g., Meurer et al., 2020). Some models consider the effects of swelling and shrinking and the impacts of tillage and subsequent consolidation at annual time-scales, but so far the temporal dynamics of macroporosity at longer time-scales arising as a consequence of the activity of biological agents (e.g., plant root

production and faunal bioturbation) have been largely neglected. The temporal dynamics of soil macropore networks are especially relevant to the pressing issue of soil degradation, so implementing such processes into models would be desirable.

Abstract

Unstable flow of water through preferential flow paths can take place in porous media as columns, also called fingers. To occur, the matric potential at the fingertip must be greater than at the surface, with a discontinuous matric potential across the wetting front. We describe the past research on unstable flow, including the criteria that cause the instability, and present a theory to explain how the contact angle changes dynamically at the front. This theory leads to more realistic models for unstable flow.

Glossary

Contact angle The angle formed between the surface and the line tangent to the edge meniscus near the soil surface. The contact angle depends on the physical properties of the soil and the liquid but also on the velocity of the wetting front.

Dynamic contact angle The contact angle that changes as a function of the velocity of the water flow. When the contact angle increases, the matric potential will increase as well and is the reason the fingertip is the wettest part of the finger.

Fingers In soils consist of wetted columns in otherwise dryer homogeneous soil.

Matric potential or capillary pressure Is the potential energy of water per unit volume relative to pure water under atmospheric pressure. It is always negative and is related to how strongly the water is being held in the soil films surrounding the grains in the soil. Water films are not present in dry soil, and the matric potential does not exist. Hence it can be considered discontinuous at the wetting front.

Preferential flow Refers to the uneven and often rapid movement of water and solutes through porous media, typically soil, characterized by regions of enhanced flux such that only a small fraction of media participates in most of the flow, allowing much faster transport of a range of contaminants, including pesticides, nutrients, trace metals, and manurial pathogens.

Unstable Flow The flow is considered unstable when disturbances are amplified and maintained in a regular pattern, i.e., a wavy infiltration front develops in column-like structures called fingers

Vadose zone Is the variably saturated zone between the ground surface and the permanent groundwater

Key points

- Preferential flow is the rule rather than the exception in soils.
- There are still gaps in the understanding of how water and pollutants move preferentially in the unsaturated zone.
- Preferential flow can occur in structured soils in regions with greater conductivity and as unstable flow in homogeneous and layered coarse-textured or water repellent soils.
- This chapter discusses unstable preferential flow.

Introduction

The importance of understanding preferential flow processes cannot be overstated, considering its relevance to groundwater recharge, crop irrigation, and vadose-zone transport of nutrients and contaminants. According to the late Louis Dekker, preferential flow is the rule rather than the exception (personal communication to T. S. Steenhuis, Summer 2008). Preferential flow affects the residence time of infiltrating water in the vadose zone and impacts the degradation and adsorption of pollutants and nutrients. Preferential flow can occur as macropore flow through locally high conductive paths or as column-type flow in a homogeneous soil due to unstable flow conditions. Both types of preferential flow are similar in that the gravity force dominates sorptive processes. In this section, we are only concerned with unstable finger flow formation driven by gravity that, according to the Science Citation Index, is not well recognized. The key terms “infiltration” and “soil” resulted in over 20,000 publications in June 2022, while only 270 of these contained the word “unstable” in addition.

Generally, it is assumed in the theory describing the water fluxes in the vadose zone that small perturbations at the wetting front during infiltration will dissipate over time. However, research has shown that this assumption is not always valid. Small perturbations can grow over time and combine to form preferential paths in homogeneous soils, commonly called fingers in the literature. However, naming them columns such as proposed by Parlange et al. (2002) in their review of earlier studies on unstable flow before 2002 would have been more appropriate (Figs. 1 and 2). The sharp boundary between the wet path and the dry soil differs from the classic soil physical infiltration front with monotonously increasing moisture content. This results from a discontinuity in matric potential at the wetting front with the dry soil, retarding the movement and resulting in moisture buildup. For gravity-driven, column-like features having a sharp boundary with the dry soil, moisture content decreases, and pressure becomes more negative monotonically in the opposite direction of the flux (Figs. 1 and 2).

Early work

Observations

In this research field, Jamison (1946) and Bond (1964) were the first to notice the presence of narrow wet “channels” or “tongues” in otherwise dry sandy soil. In the experiments of Hill and Parlange (1972), the column persistence was controlled, given sufficient time for vapor transport to establish an equilibrium by hysteresis between the soil water in the finger (on a wetting branch) and the outside (on a drying branch, Liu et al., 1995; DiCarlo et al., 1999). Parlange et al. (2002) showed that the width of the two-dimensional columns, d , in slab chambers is usually well approximated by:

$$d = \frac{\pi S^2}{K_s(\theta_s - \theta_i)} \frac{1}{1 - \frac{Q}{K_i}} \quad (1a)$$

Which can be simplified to

$$d = \frac{2\pi}{\alpha} \quad (1b)$$

Fig. 1 Fingers formation and development in coarse sand below a fine sand layer in a flow slab experiment after: (a) 2 min, (b) 5 min, and (c) 15 min of water infiltration. The fine sand layer where water was uniformly distributed is not shown. The color indicates the moisture contents, with red the closest to saturation. Then the colors for decreasing moisture contents are yellow, light green, light blue, dark blue, and black. Reproduced from Glass RJ, Steenhuis TS and Parlange JY (1989) Mechanism for finger persistence in homogeneous, unsaturated, porous media: Theory and verification. *Soil Science* **148**: 60–70.

Fig. 2 Finger flow pathways (dyed blue with the infiltrating water) in a soil profile in coastal sediments in Delaware. Water moves down like fingers and then encounters a coarser layer over which it flows sideways (Picture made by Jan Boll).

where S is the sorptivity, Q is the imposed water flux, and K_s is the saturated conductivity of the coarse sand layer, θ_s is the near-saturated moisture content at the fingertip and θ_i is the initial moisture content, α is a constant in the exponential unsaturated hydraulic conductivity equation and is approximately equal to the reciprocal of the height of the capillary fringe. For the three-dimensional fingers, the π should be replaced by 4.8.

Saffman and Taylor (1958) were the first to show instability in a Hele-Shaw cell (mimicking a porous medium). Their experiment with nearly 4000 citations in Google Scholar profoundly impacted our understanding of instability phenomena in porous media. There are, however, several significant differences between this ideal study and unstable flow in soils. In Hele-Shaw cells, hysteresis is irrelevant; consequently, fingers widen behind the wetting front and merge in Hele-Shaw cells. Hence, the length of the fingers remains approximately the same when moving downwards. In soils, downward moving fingers have the same width and remain distinct. Another complication was the use of oil by Saffman and Taylor, leading to the expression “viscous fingering”. Since similar patterns can be obtained with water infiltrating in unsaturated soil with entrapped air, viscosity is not a very important characteristic for the instability to form.

Conditions for wetting front instability

For gravity-driven column-like wetted volumes, the stability criteria of Saffman and Taylor (1958) can be written for the case where water moves down under gravity and the viscosity of air is negligible (Parlange and Hill, 1976; Parlange et al., 2002),

$$K_s > Q \quad (2)$$

Raats (1973) postulated that flow is unstable when the pressure at the wetting front, h_L is greater than the pressure at the surface h_0 (i.e., is more negative at the surface than at the wetting front):

$$h_0 - h_L < 0 \quad (3)$$

Raats (1973) derived the condition in Eq. (3) by assuming that velocity of a homogeneous, stable front, v_w increased with depth for the perturbation to grow in time and become unstable:

$$\frac{dv_w}{dL} > 0 \quad (4)$$

where L is the wetting front depth. Raats (1973) also noted that the increased contact angle for dry water repellent soils would also meet the condition in Eq. (3).

Checking stability criteria using experimental evidence

Several researchers have confirmed the finding of Hill and Parlange (1972). In the laboratory, unstable fingered flow occurs when a fine layer restricts the flow to dry, coarse sand and under field conditions in layered soils, confirming Eqs. (2) and (4). The fine layer restricts the flow (Eq. 2), and the wetting front velocity is smaller in the fine soil than in the coarse soil below (Eq. 4).

Another method to reduce the flow rate is to apply water at less than the saturated conductivity (Selker et al., 1992a). They and others have shown that this technique will produce unstable fingered flow in dry, wettable sandy soils. In this case, small amounts of initial moisture strongly inhibited instability pattern development (Yao and Hendrickx, 1996; Selker et al., 1992a) also measured that the capillary pressure at the wetting front was less than above the fingertip and confirmed the validity of Eq. (3). However, the downward velocity of the finger was constant; thus, the condition in Eq. (4) that the velocity increased with depth was not met.

Finally, following the instability criteria in Eq. (2), experimentally increasing the flow rate to near-saturated hydraulic conductivity produced monotonic wetting profiles in wettable soil (Geiger and Durnford, 2000). However, unlike the stability criteria in Eqs. (2) and (4), extremely small flow rates of less than 0.12 mm/h did not result in fingered flow (Hendrickx and Yao, 1996).

As postulated by Raats (1973), Dekker and coworkers in the early 1990s, Dekker and Ritsema (1994) and Ritsema and Dekker (1994) showed that soil water repellency in the field caused unstable flow through permanent paths. Since these early experiments, other researchers have found that unstable fingered flow occurred in water repellent soils of various textures, confirming the validity of the condition stated in Eq. (3).

In addition to these field experiments, slab chambers experiments filled with sand of different water repellency degrees were conducted in the late 1990s by Bauters et al. (2000) and Wang et al. (1998). Soils can have different degrees of water repellency depending on the contact angle. It is often called subcritical water repellency when the contact angle is less than 90 degrees. As few as three water repellent sand grains in a hundred caused the soil to become subcritical water repellent and resulted in wetting front instability (Bauters et al., 2000). In the Bauters experiments, water ponded on a strong water repellent soil surface before it infiltrated suddenly. Thus, the unstable flow in water repellent sands does not satisfy the instability criteria outlined in 4. Eq. (2) is immaterial when water ponds at the surface. Condition 3 of greater pressure at the top than at the wetting front was met (Bauters et al., 2000).

Entrapped air also caused finger formation. The air is entrapped when a soil surface is wetted uniformly, and the wetting front is saturated in an otherwise confined domain. In these cases, the downward movement of the wetting front compresses the air underneath, as shown experimentally by Wang et al. (1998). These fingers are therefore not caused by instability criteria set in Eqs. (2)–(4) since they do not show the high moisture content at the front.

Dynamic contact angle

In all cases where gravity-driven fingers form under atmospheric pressure, the moisture content and pressure—when measured—were greater at the fingertip than some distance above it, as postulated by Raats (1973) and is a characteristic of gravity-driven fingers. Criteria in Eqs. (2) and (4) were not always met in fingered flow experiments.

The implicit assumption for establishing the instability criteria in the 1980s was that Darcy's law and the mass conservation could describe the unstable phenomena at the wetting front. Some studies (e.g., Geiger and Durnford, 2000) inferred that the capillary pressure of the edge of the finger (including the fingertip) is discontinuous. For discontinuous pressure, the capillary pressure below the wetting front is independent of that at the wetting front. The capillary pressure, h (m), under static conditions at the discontinuous wetting front capillary pressure can be expressed as (Raats, 1973):

$$h = -\frac{2\sigma \cos \theta}{\rho g r} \quad (5)$$

where σ is the surface tension (N/m), ρ is the density of the fluid (kg/m³), g is the gravitational constant (m/s²), r is the pore diameter and is the θ contact angle. For a moving wetting front, the capillary pressure can be expressed as a function of the dynamic contact angle, θ_d

$$h = -\frac{2\sigma \cos \theta_d}{\rho g r} \quad (6)$$

The dynamic contact angle is dependent on the static contact angle, surface tension, viscosity, and the velocity of water in the pore (Hoffman, 1975) and can be expressed based on experimental evidence (Baver et al., 2014) as

$$\theta_d = \theta_s + \left(1 - \frac{\theta_s}{\pi}\right) \arccos [1 - 2 \tanh (4.96 Ca^{.702})] \quad (7)$$

where θ_s is the static contact angle (radians) of the water with silica grains, and Ca is the dimensionless capillary number defined as:

$$Ca = \frac{\mu V}{\sigma} \quad (8)$$

where μ is the viscosity of the liquid (Pa s), V is the contact line velocity (m/s), and σ is the surface tension (N/m) between air and water.

To find the velocity of the water in the pores, experimental observations with a high-speed camera by Moebius and Or (2012) have shown that water moves as bursts at the wetting front with velocities in pores that are more than 50 times faster than the average pore velocity. The pore velocity of the water at the wetting front can be obtained for small fluxes by assuming that water is flowing through one pore at a time. From a mass balance point of view, when water goes down one pore at a time, the minimum pore velocity is equal to the flux (Q , m^3/s) in the finger divided by the area of the pore neck. It might be greater when there is a pause between the breakthroughs (Steenhuis et al., 2013). By calculating the velocity this way, we can use Eqs. (7) and (8) to find the dynamic contact angle, θ_d . Substituting θ_d in Eq. (6), the capillary pressure at the wetting front can be found. The moisture content can be calculated using the soil characteristic curve.

Thus, the assumption that the velocity in the pore affects the dynamic contact angle leads directly to the instability criteria postulated by Raats (Eq. 3): The dynamic contact angle increases the contact angle at the wetting front and thereby lowers the capillary pressure at the wetting front below that of the capillary pressure in the finger itself.

The theory of the dynamic contact angle was tested by Steenhuis et al. (2013). They calculated the capillary pressures at the wetting front with Eqs. (6)–(8) for the extensive experiments in 1.3 cm columns carried out by DiCarlo (2007). The observed and predicted capillary pressures are given in Fig. 3 for the initial moisture contents ranging from 0 to $0.14 \text{ cm}^3 \text{ cm}^{-3}$. The pore neck diameter was fitted for one experiment. The static contact angle was 50° for dry soil and decreased linearly to 20° for moisture contents of 9% and greater. The observed and predicted data followed the same trend.

The theory also explains previous experimental findings. One of the empirical findings was that finger formation is suppressed in wettable soils with residual moisture (Hendrickx and Yao, 1996). These small amounts of water form films around the grain, making the pressure across the wetting front continuous and resulting in monotonic infiltration profiles with increasing moisture content and capillary pressure towards the soil surface.

Glass et al. (1989) and others showed that wettable soils with uneven moisture distribution generated by previous fingered flow events would infiltrate again through these fingers. Water enters the finger under lower matric potential than the dry soil because of the films around the grains in the finger than are not present in the dry sand. Only when the soil dries out can the path of the finger be at a different location.

Although both wettable and water repellent soils experimentally produce gravity-driven fingered flow, the behavior at the wetting front is different. In water repellent soils, the contact angle is greater in dry soil than in wet soil. Therefore, the instability criterion in Eq. (3) is met independently of a dynamic contact angle tied to the pore velocity as postulated already by Raats (1973). Only for subcritical water repellent soils, the increase in contact angle due to the pore velocity might be significant.

Modeling gravity-driven fingers fingered flow

Since Hill and Parlange (1972) published their observations of gravity-driven fingers in well-sorted sands, researchers have developed models to simulate this unstable phenomenon with the decreasing water content and matric potential opposite the flow direction. The models and analytical solutions (called models for short) can be distinguished into roughly three categories: (1) continuum models where pressure across the wetting front is continuous, and the water flow is simulated for the complete

Fig. 3 Observed and predicted capillary pressures in the fingertip as a function of moisture content and imposed fluxes. Observed data (symbols) are from infiltration experiments by DiCarlo (2007) in small 1.3 cm wide columns filled with 20/30 sand and are averages over all replicates as each flux. Predicted lines are based on Eqs. (6)–(8).

profile. (2) semi-continuous models that take the matric potential discontinuity at the wetting front as a given and use soil physics theory to predict the water movement behind and in front of the wetting front, and (3) pore network models that adapt the contact angle at the finger edge.

Continuum models

When the pressure in the soil is continuous, the Richardson-Richards equation applies. However, the equation is unconditionally stable and can only produce a monotonic temporal change in saturation, i.e., the moisture at each point in the soil profile can either increase or decrease. In contrast, as discussed in the previous section, gravity-driven fingering is characterized by an abrupt change in saturation at the wetting front and nonmonotonic saturation temporal change within the fingers (DiCarlo, 2013). As a result, solution obtained using Richardson-Richards' equation cannot produce a gravity-driven unstable flow. Several approaches tackled this limitation by adding a term to the Richardson-Richards equation. A drawback of the continuum models is that they do not reproduce the sharp wetting front.

Semi-continuum modeling

Semi continuum models treat the wetted finger and the surrounding soil as discrete entities. Selker et al. (1992b) published the first type of this model. They predicted the decreasing water content behind the wetting front with the Richardson-Richards equation by using a moving coordinate system, constant pressure at the wetting front, and a finger width predicted by using the equation of Parlange and Hill (1976). DiCarlo (2013) extended the approach of Selker and coworkers by adding pore-scale physics to the continuum flow equation at the wetting front. Kmec et al. (2021) used the DiCarlo approach and combined ideas from continuum mechanics and invasion percolation models to divide the modeling domain into finite subdomains, each represented by average capillary pressure values. Brindt and Wallach (2020) adapted the Stefan heat-flow moving boundary problem boundary approach for characterizing the wetting front advancement of gravity-driven unstable flow by controlling the contact angle at the wetting front. The main disadvantage of the semi continuum models is that matric potential at the front cannot be determined independently and must be obtained from experimental results.

Pore network models

Pore network models have pore and throat elements that can only have discrete saturation states. This modeling approach produced finger-like wetting patterns with drying behind the tip for all fluxes, contrary to the experimental results. Other pore network models incorporated rules that allowed partial wetting of pores (Hughes and Blunt, 2000).

Common to all the above mentioned models is that the wetting front is retarded. The retardation in continuum models is achieved by ad-hoc measures of which the physical validity remains in doubt (DiCarlo, 2013). Pore-based network models have been relatively successful in simulating the transition between monotonic and unstable profiles as a function of the flux. Still, it requires a more robust description of the interface of the two fluids (DiCarlo, 2013). The dynamic contact angle theory presented can be used as a framework for modeling the pressures at the interphase of the two fluids for better performance of pore network models.

Summarizing remarks

Water tends to flow in preferential paths since it is thermodynamically more favorable. Unstable gravity-driven fingered flow is one of the consequences. Unstable flow occurs when the matric potential at the wetting front is greater than at the surface, made possible by a matric potential discontinuity across the wetting front due to the lack of water films in the dry soil. In monotonic moisture content profiles, water films aid the advance of the water. When water is strongly adsorbed to the grains in dry soil (and the distinct water films still need to be formed), water movement through the pore necks is retarded. Since the resistance to flow is different among pore necks, water will flow through one pore neck at a time in a short time. The rapidly flowing water will cause a flattening of the meniscus compared to the pores behind the front lowering the matric potential. Since the lower matric potential is in equilibrium with greater water content, the tip of the finger is wetter than the remaining part.

Since the quantity of water has become limited in many parts of the world, water conservation practices such as wastewater irrigation will become more prevalent. Organics in the wastewater can make soils more water repellent. Thus, we expect that areas irrigated with wastewater will show preferential flow independent of the soil texture, thereby reducing irrigation efficiency, as noted by Jamison almost a century ago. Therefore, understanding unstable flow processes may help drain less water from soil profiles, saving water and keeping the groundwater free of additional pollutants.

Abstract

Soil is the thin and biologically active skin of our Green Planet. Soil, by virtue of its intrinsic fertility, plays a key role in sustaining our primary-production systems that seek to feed our growing populations. To enhance the productivity of these agricultural systems, irrigation water, fertilizers, salts, and pesticides are often applied to crops growing on soil. As well, soils are sometimes used for the disposal, either intentional or accidental, of certain waste products. Also the soil surface is the depository of atmospheric compounds that might either be natural, such as salt, or compounds from human activities, such as sulfur. Since soil lies astride the main pathway along which rainwater leaches to either groundwater or surface water bodies, the water quality of these receiving water reserves is strongly influenced by land management, and the myriad of interlinked water-transport processes and chemical-exchange mechanisms that operate in the soil domain. Development of sustainable land-management strategies, and the design of environmental-protection protocols, demand that leaching process be well understood.

Key points

- Globally some 720 mm of rains falls on soil every year. Of this, some 310 mm on average either drains through the soil, or runs off into receiving water bodies.
- The flows of agrichemicals, nutrients and salts have their origin in the surface soil, and their transmission to receiving waters is by leaching with the drainage water.
- Drainage flows and leaching pathways are chaotic in the structured soils that typify the earth's surface, and this leads to rapid and far-reaching leaching.
- Novel measurement devices and modern modelling approaches are providing new information and improved understanding of drainage and leaching.
- Better land management practices are needed to maintain aquifer recharge and protect groundwater quantity, and to prevent degradation of ground and surface waters through the leaching of nutrients, agrichemicals, and salts.

Introduction

The world is facing a wicked trilemma. We need to feed and sustain a rapidly growing population, and we must adapt to the exigencies of climate change, all the while functioning within the planet's safe operating space. In 2009 the Stockholm Resilience Institute published a framework to assess how, across seven control variables, the world was operating relative to the planetary boundaries for a safe operating space (Rockström et al., 2009). They updated this in 2015 (Steffen et al., 2015), and this assessment is presented here in Fig. 1. The greatest exceedance of the planetary boundary layer is for biosphere integrity, closely followed by the biogeochemical flows of nitrogen and phosphorus. Rockström et al. (2009) commented that "... modern agriculture is a major cause of environmental pollution, including large-scale nitrogen- and phosphorus-induced environmental change." They added that "... the additional amounts of nitrogen and phosphorus activated by humans are now so large that they significantly perturb the global cycles of these two important elements."

Fig. 1 The current status of seven control variables relative to the planetary boundaries for Earth's safe operating-space. The green sectors are within the safe boundary, with orange being increasing risk, and red is high risk. Here P is phosphorus, N is nitrogen, E/MSY is extinctions per millions species per year, and BII is the Biodiversity Intactness Index. Based on Steffen W, Richardson K, Rockström J, Cornell SE, Fetzer I, Bennett EM, Biggs R, Carpenter SR, de Vries W, de Wit CA, Folke C, Gerten D, Heinke J, Mace GM, Persson LM, Ramanathan V, Reyers B, and Sörlin S (2015) Planetary boundaries: Guiding human development on a changing planet. *Science* 347:6219. doi:10.1126/science.1259855.

The biogeochemical flows of nitrogen and phosphorus, as well as other agrichemicals have their origin in the critical zone of the top few meters of our soils, and their transmission to receiving water bodies is by leaching processes through soil. In addition, the leaching of salts resulting from excessive irrigation using saline waters, especially in arid and semi-arid regions, is resulting in soil salinity and shallow groundwater problems that will require effective management of water and salt in order to avert global food-security issues (Wichelns, 2015).

Soil is the thin and biologically active skin of our Green Planet. Soil, by virtue of its intrinsic fertility, plays a key role in sustaining our primary-production systems that seek to feed our growing populations. To enhance the productivity of these agricultural systems, irrigation water, fertilizers, and pesticides are often applied to crops growing on soil. As well, soils are sometimes used for the disposal, either intentional or accidental, of certain waste products. Also, the soil surface is the depository of atmospheric compounds that might either be natural, such as salt, or compounds from human activities, such as sulfur. Since soil lies astride the main pathway along which rainwater leaches to either groundwater or surface water bodies, the water quality of these receiving water reserves is strongly influenced by land management, and the myriad of interlinked water-transport processes and chemical-exchange mechanisms that operate in the soil domain. Development of sustainable land-management strategies, and the design of environmental-protection protocols, demand that leaching process be well understood.

Leaching encompasses the gamut of biophysical mechanisms and chemical exchange processes that can result in altered chemical concentrations in any pore-water that is percolating through soil. There are two aspects to leaching; the quantity of the water that is draining through the soil and destined for subterranean, or surface water bodies; and the chemical concentration, or quality, of that pore water. We use the term leaching to encompass these two meanings; the deep seepage of water, more commonly called drainage, plus the leaching export of chemicals carried by that drainage.

In this chapter, we first explore the controls on the quantity of drainage water quitting the base of the rootzone (D , mm). We then describe the chemical processes that lead to changes in the quality of that drainage water. For risk assessment purposes it is necessary to know both the concentration of a chemical in the leachate (C , mol m⁻³), plus the total chemical load (per unit ground area) that is moving to receiving water bodies (M , mol m⁻²; or more commonly in kg ha⁻¹). The total leaching of chemical, M (load), is the product of D (quantity) and C (quality). Thus, in our discussion of leaching processes, we need to consider both the transport of water, along with the chemical processes operating in soil. We outline, with examples, the mathematical description of transport processes, and the chemical exchange mechanisms that determine the leachate load.

Physically, soil is a porous medium comprising a complex arrangement of the three phases of solid, liquid and air. Much to the chagrin of scientists, convective and diffusive flow through soil does not behave in the uniform and isotropic way assumed by their simple, theoretical descriptions. Rather, aggregates, cracks and macropores serve to create an apparently chaotic flow regime that leads to rapid and far-reaching transport of chemicals. Modelling methods that account for this preferential flow are described. The application of such models for risk assessment purposes is also discussed. We conclude with a modelling assessment of the risks posed to groundwater by the leaching of the pesticides that are applied to grapes growing on soil above an unconfined aquifer.

Drainage quantity

Globally, an average of some 720 mm of rainfall (RF , mm) falls on soil each year. The many nooks and crannies in the soil provide it with a capillary attractiveness so that there is some tendency for the infiltrating rainwater to be absorbed by the soil, near the surface. The ever-present force of gravity tends to draw complementary water deeper into the profile beyond the grasp of the roots. On balance, about 410 mm of the global average rainfall is lost back as vapor to the atmosphere, either by direct free-water evaporation from the soil and directly off plant surfaces (E , mm), or by transpiration through plants (T , mm). Any transpired water must first have been captured from the soil by the plant's roots. The complement of evaporation, namely drainage, D , and runoff, R , averages therefore about 310 mm per year, since on an annual timescale the change in soil-water storage is negligible. Drainage water acts a vehicle, carrying with it passenger solutes that can leach the soil of chemicals that may compromise the quality of receiving waters. For productive systems, rainfall might be augmented by irrigation (I). Indeed, irrigation comprises about 80–85% of the world's consumption of fresh water. And unfortunately some 20% of global gross irrigation water-usage comprises nonrenewable groundwater extraction (Wada et al., 2012), and this nonrenewable contribution more than tripled between 1960 and 2000.

Both for production purposes and environmental protection, it is critical to determine whether the partitioning of rootzone water, and its dissolved solutes, is either into the plants by uptake, or dispatch by drainage toward groundwater, D . Along with the surface evaporation of water, roots are the arbiters of this partitioning, and they largely determine water and solute fate (Fig. 2). In simple terms, roots penetrate the soil to some effective depth, z_R (mm). From within this rootzone they extract liquid water, and some dissolved solutes. Thus rhizosphere processes critically affect both the quantity and quality of leachates leaving the rootzone.

Fig. 2 The fluxes of water in the rootzone. Here the effective depth of rooting is z_R . Inputs into the rootzone include rainfall (RF), as well as irrigation (I) in some cases. Not all of the applied water might infiltrate, as there could be runoff (R). Evaporative losses are either by direct evaporation of water from the soil surface (E), or by transpiration from plants (T). Drainage of water from the base of the rootzone toward groundwater, D , carries with it leaching solutes.

The water balance of the rootzone, over a given time interval Δt , can be written to find the drainage at depth z_R , as

$$D = RF + I - R - E - T - \Delta S, \quad (1)$$

where ΔS is the change, over Δt , in the storage of soil water in the rootzone (mm). The variation in the storage of water can be found from the change in the soil-water content profile, $\theta(z)$ ($\text{m}^3 \text{m}^{-3}$), over Δt , integrated from the surface down to the base of the rootzone,

$$\Delta S = \int_0^{z_R} \Delta \theta(z) dz. \quad (2)$$

Thus the quantity of drainage, D , is implicitly linked to the weather (RF , R , E , and T), as well as to the nature of the soil and the vegetation cover, plus the effective depth and distribution of plant roots.

At a mechanistic level, this interplay between soil-water diffusion and convection, and root-water extraction, can be described by the Richardson-Richards equation,

$$\frac{\partial \theta}{\partial t} = \frac{d\theta}{dh} \frac{\partial h}{\partial t} = \frac{\partial}{\partial z} \left(K(h) \frac{\partial h}{\partial z} \right) - \frac{\partial K(h)}{\partial z} - U(h(z), t) \quad (3)$$

where h (mm) is the soil-water pressure head, which is a function of the soil's water content, and K (mm s^{-1}) is the pressure-head dependent, soil-water conductivity function. The first term on the right-hand side describes the diffusive nature of the capillary-induced movement of water through soil. The second term accounts for direct convection in response to gravity. The last term, U (mm s^{-1}), is the depth-dependent extraction of water by plant roots. Many forms have been proposed for U (Feddes et al., 1976), and all rely on the theoretical insight provided by Gardner's (1960) seminal work on the uptake of water by roots.

The Richardson-Richards equation is the theoretical scheme used to model and predict the partitioning of soil-water fate into either plant uptake (T), or drainage (D) (Clothier and Green, 1997).

Leachate quality

The chemical concentration of the soil's pore-water solution, C , depends on a complex of linked interactions between transient transport processes, chemical exchange mechanisms, as well as production, extraction and degradation reactions. For any chemical species, the convection-dispersion equation describes the resident concentration at any time and location in the soil as

$$\frac{\partial \theta C}{\partial t} + \frac{\partial \rho S}{\partial t} = \frac{\partial}{\partial z} \left(\theta D_s \frac{\partial C}{\partial z} \right) - \frac{\partial q_w C}{\partial z} + \sum \Gamma_i \quad (4)$$

where S is the concentration of chemical that is retained by the soil matrix (mol kg^{-1}), ρ is the soil's bulk density (kg m^{-3}), D_s is the solute's diffusion-dispersion coefficient ($\text{mm}^2 \text{s}^{-1}$), q_w is the water flux density (mm s^{-1}), and Γ_i is the source/sink term for the i reactions that can produce, extract or degrade the chemical species concerned ($\text{mol m}^{-3} \text{s}^{-1}$). The structure of this formula (Eq. 4) highlights the inextricable link between water movement (q_w) (Eq. 3), and chemical-transport processes.

As well, Eq. (4) accounts for the link between the chemical concentration in the soil solution (C), and the amount of chemical that is adsorbed to the surfaces of the soil's matrix (S). This relationship is called the adsorption isotherm. One commonly used form that describes this exchange process is the Langmuir isotherm;

$$S = S_{\max} \frac{mC}{1 + mC} \quad (5)$$

where $S_{\max}$ is the maximum adsorption (mol kg^{-1}), and m is an empirical constant ($\text{m}^3 \text{mol}^{-1}$). Often, however, for simplicity, or in an absence of better information, a linear isotherm is assumed,

$$S = K_D C \quad (6)$$

where K_D is called the distribution coefficient ($\text{m}^3 \text{kg}^{-1}$).

Eqs. (3) and (4) provide us with a mathematical framework that is commonly used to interpret and predict the leaching processes that determine the quantity of leachate (D), and the leachate load of chemical (M).

Preferential leaching processes

The macroscopic theory, on which Eqs. (3) and (4) is based, requires that the soil be a uniform isotropic medium. Unfortunately, soil is a highly structured medium, such that the three phases of solid, liquid, and air are anisotropic. And there is often a high degree of connectedness between these phases. Soil structure is typically characterized by aggregates, fractures, and biogenic macropores (Fig. 3).

The spatial topology of the macroporous networks that typify structured-soil determines the speed and extent of preferential flow processes. As a result of local non-equilibrium processes, there can be more rapid and deeper-than-expected leaching of surface-applied chemicals, relative to that predicted by Eqs. (3) and (4).

Fig. 3 Soil structure is characterized either by aggregates (left), or macropores and fractures (right). Such structure results in rapid and far-reaching transport processes that lead to preferential leaching of applied chemicals. In such structured soils, there is meanwhile likely to be reduced leaching of chemicals produced from within the soil's matrix.

Not all of the soil's pore water would therefore seem to be actively involved in water transport and chemical exchange. Aggregates and macropores can create a wide spectrum of pore-water velocities associated with a solution that is either invading the soil, or leaching from it. In an aggregated soil, the more-rapid water-flow paths will be those that are connected throughout the inter-aggregate domain. So inter-aggregate water will preferentially wend its way around the aggregates, which tend to possess smaller, yet albeit connected intra-aggregate pores. These would not seem to be as effective at leaching chemicals from rootzone soil, because the flow velocities are lower and the connected path-lengths shorter.

Alternative non-mechanistic transfer-function schemes have been developed for modelling the preferential leaching of chemicals through structured soil. Process-based transport schemes are difficult to parameterize, and so transfer-function models have been considered because they are less data-intensive, and they can support either a deterministic or stochastic framework. The text of [Jury and Roth \(1990\)](#) provides a comprehensive treatment of transfer functions and solute movement through soil, and describes how the solute travel-time probability density function can be taken as a fundamental property of the soil system.

Pedogenic and biogenic processes can impart upon soil a macroporous structure characterized by a longitudinal connectedness. The enhanced mobility of flow down these variously sized macropores, as predicted by Poiseuille's Law of flow through a pipe, is abetted by macropore connectivity to produce preferential transport of the invading solution, or enhanced leaching of some part of the resident solution.

In an illustrative study of preferential leaching in the laboratory with undisturbed cores of soil growing pasture, [Scotter and Kanchanasut \(1981\)](#) used two dye tracers to mimic leaching. Methylene blue dye, applied in free-water ponded on the soil's surface ($h_o = 0$), was found to stain only a small volumetric fraction of the soil's volume ([Fig. 4](#)). When water containing rhodamine-B dye was applied to the soil in water at the slight unsaturated surface potential of -20 mm, the pattern of leaching was found to involve a larger volumetric fraction of the soil's porosity. Obviously, leaching in structured soils can, depending on hydraulic conditions, involve differing volumes of the soil's wetted porosity.

One of the most-popular mechanistic models currently used to model the preferential leaching that results from either the presence of aggregates or macropores, is that presented by [van Genuchten and Wierenga \(1976\)](#). Occam's razor is simply used to cut the soil's volumetric water content θ ($\text{m}^3 \text{m}^{-3}$) in two. This binary assumption does not account for changes in the leaching processes as a function of the soil's degree of unsaturation (cf. [Fig. 4](#)), but it does better represent the preferential leaching processes that prevail in field soils. The great simplicity of this model is that one fraction of the soil's water, θ_{im} ($\text{m}^3 \text{m}^{-3}$), is considered, for leaching purposes, to be effectively stagnant. The complementary portion of the soil's water, θ_m ($\text{m}^3 \text{m}^{-3}$), is deemed to be mobile, as might be imagined of that water which is between the aggregates, or flowing in the macropores.

A two-domain approximation for the leaching of a conservative solute under steady flow at pore-water velocity v_m , (mm s^{-1}), was given by [van Genuchten and Wierenga \(1976\)](#) as.

$$\theta_m \frac{\partial C_m}{\partial t} + \theta_{im} \frac{\partial C_{im}}{\partial t} = \theta_m D_s \frac{\partial^2 C_m}{\partial z^2} - v_m \theta_m \frac{\partial C_m}{\partial z}, \quad (7)$$

Fig. 4 Contrasting patterns of the leaching of two dyes through a 120 mm diameter core of undisturbed soil. The dark area was stained by a dye tracer contained in saturated flow from a free-water pond at the surface ($h_0 = 0$), and the stippled area was from dye leached by unsaturated water applied at the slight negative head of $h_0 = -20$ mm. From Scotter DR and Kanchanasut P (1981) Anion movement in a soil under pasture. *Australian Journal of Soil Research* 19:299–307.

where C_m and C_{im} are the concentrations of inert chemical in the mobile and immobile domains, and $v_m = q_w/\theta_m$. It is assumed that molecular diffusion in the direction of leaching in the mobile domain is negligible, and that the only mechanism to transfer solute between domains is, for analytical convenience, limited to a diffusion-like process that can be described by.

$$\theta_{im} \frac{\partial C_{im}}{\partial t} = \alpha (C_m - C_{im}) \quad (8)$$

where α (s^{-1}) is a first-order mass transfer coefficient.

To measure θ_{im} independently, Clothier et al. (1992) proposed using a tracer-filled tension disk-permeameter to allow leaching into the soil of a solution at some concentration C_m . Ignoring any effects that might accrue from interdomain diffusion (Eq. 8), the flux concentration in the mobile domain in the soil just under the disk, would be C_m . Thus by removing soil samples from under the disk, and determining the average resident concentration of solute C^* , the mobile fraction could be found using the partitioning formula

$$\theta C^* = \theta_m C_m + \theta_{im} C_{im}. \quad (9)$$

If a tracer not initially present in the soil were used, and if diffusive exchange (Eq. 8) were considered sufficiently weak, then C_{im} should remain essentially zero over the time scale of the experiment. So,

$$\theta_m = \theta \left(\frac{C^*}{C_m} \right), \quad (10)$$

via which θ_m can be obtained independently from measurements immediately under the disk of just C^* and θ . Their results for a silt loam suggested that for leaching, θ_m/θ is about 0.7–0.75 at a pressure head of $h_o = -40$ mm. Only about three-quarters of the soil's water-filled porosity appeared to be actively involved in leaching. This qualitatively corroborates the cross-sectional staining areas in Fig. 4, where it could be presumed that about 50% of the area were pore-space, and of that only about 75% was stained by dye.

Subsequently, Jaynes and Horton (1997) added a novel aspect to this technique. Through the use of the sequential invasion of i inert tracers into the same soil under the permeameter, they showed how differences in the respective resident concentrations of C_i^* would reflect the rate of diffusion, α , into the immobile domain. The resident concentration in the soil of any tracer i would reflect the diffusion that had taken place during the time t_i it had been present in the mobile domain. From a regression of the measurements using

$$\ln \left[1 - \frac{C_i^*}{C_{m,i}} \right] = \frac{-\alpha}{\theta_{im}} t_i + \ln \left[\frac{\theta_{im}}{\theta} \right], \quad (11)$$

they could deduce both θ_m and α . From many experiments on various soils, they found α to range between about 5×10^{-7} and $5 \times 10^{-6} s^{-1}$.

For aggregated soils, Jarvis (1994) presented a numerical model, the aptly named MACRO, which allows convection between the inter-aggregate mobile zone and the intra-aggregate pores. This convection is considered gravity-free, and is simply driven by water content differences between the respective domains. Solute transfer between these domains is allowed both by diffusion, as well as by direct convection with the transferring water. By simulation, Jarvis (1994) concluded that "... at short times, macropore flow increases leaching of non-reactive solute. At longer times, leaching is reduced by macropore flow [and it is] critical to account for the effects of macropore flow in clay soils on the leaching of sorbing, and degrading compounds."

Field measurement devices

Better management is needed as to how we use nitrogen and phosphorus, as well as manage salt, to grow the crops required to feed the world's burgeoning population within the safe operating-space for planet Earth (Fig. 1). The management thinker Peter Drucker stated that "you can't manage what you can't measure." Therefore there is an imperative to measure leaching processes so that we can improve land-management practices in relation to the biochemical flows of nitrogen and phosphorus (Steffen et al., 2015), salts, and pesticides.

Leaching, in terms of kg of nutrients, active ingredients, or salt per hectare of land per unit time, is the product of the drainage of water, in m of depth equivalent ($\text{m}^3 \text{m}^{-2}$), times the concentration, in mg L^{-1} , of the nutrients, pesticides, or salt in the drainage water.

By encapsulating a representative volume of soil in a sealed container it is possible to monitor drainage, and to measure the concentration in the leachate leaving the base of the enclosed soil. This set-up is known as a lysimeter. Lysimeters enable quantification of the complete mass balance. Lysimeters come in a variety of forms: repacked soil, or undisturbed cores; free-draining base, or controlled tension drainage; weighable, or non-weighing; shallow ones for grasses, or deeper ones for trees. A Special Section of the Vadose Zone Journal (Pütz et al., 2018) highlighted the roles that lysimeters can play in quantifying evaporation and evapotranspiration, chemical leaching and recharge, plus modelling and process evaluation. Pütz et al. (2018) concluded that lysimeters bridge the gap between laboratory studies and field measurements. Lysimeters are expensive in terms of capital costs and time requirements, and so they are rarely used for monitoring of leaching across landscapes.

A cheaper and simpler way to infer leaching losses is to sample the soil solution through using suction cups. Suction cups are constructed out of a porous medium such as ceramic, or a fritted material, that when inserted into the soil allows ingress of the soil solution into a reservoir when a suction is applied to the cup. The chemical concentration in the aliquot withdrawn from the soil solution is presumed to be the flux concentration of the solute that would be leaching. Furthermore, to calculate the areal loading of the leaching of solutes, there needs to be a contemporaneous measure of the drainage rate. This can be done via Darcy's Law, or using a water balance estimate, or predictions through transport modelling. Skaggs et al. (2002) noted that the "... solute concentrations measured with porous cup solution samplers are known to be affected by the magnitude, method and duration of the applied suction." Indeed, the chemical concentration within the suction cup is likely to be an admixture of the mobile flux-concentration, and the immobile resident-concentration of solute in the soil solution. There can also be other practical issues. Duwig et al. (2000) used suction cups to infer nitrate leaching through an uplifted coral atoll in the South Pacific. The soil there is very permeable, and this created measurement difficulties for there was a narrow time-window during the drainage cycle when the suction cup could actually withdraw any aliquots from the soil solution. In a study of nitrate leaching under irrigated sugarbeet in Montana, USA, Jabro et al. (2016) observed high variability between suction-cup replicates in the measured nitrate-N concentrations. They concluded that suction-cup samplers are not recommended in heterogeneous soils that exhibit preferential macroporous flow-patterns.

A cheaper alternative to enclosed lysimeters are the so-called pan lysimeters where a collection receptacle is inserted into the soil profile and water is collected into a reservoir through gravity (Richards, 1950). These devices are also known as 'zero tension' lysimeters, because water enters the collection container as free drainage-water. This free-water sampling of the draining soil solution by pan lysimeters means that measured flux-concentration of chemicals in the reservoir might not be the true flux-concentration of solutes moving through the soil under both gravitational and capillary forces.

Earlier, Ivie and Richards (1937) had conceived of the 'equilibrium tension' lysimeter for field use, whereby the drainage water could be drawn through a porous plate or membrane under a controlled vacuum. This has led to the more-recent development of the water flux-meter, a passive capillary-wick lysimeter, which Gee et al. (2009) described as "... a compromise between the complications and expense of equilibrium tension lysimeters and the simplicity of the less accurate pan lysimeters." Gee et al. (2009) provided a comprehensive and critical review of the efficacy and performance of the various forms of the passive-wick drainage fluxmeter (DFM).

Green et al. (2010) described their version of a DFM (Fig. 5). The DFM comprises a convergence ring to align the flow vertically, under which is a funnel containing a mix of sand and diatomaceous earth within which the untangled threads of a fiberglass wick are distributed. The wick length is 600 mm and this feeds into a tipping spoon to record the drainage hydrograph, before the soil solution is then stored underneath in a reservoir, from which it can be pumped to the surface using a vacuum pump. The leachate concentration in the drainage solution can then be measured.

Nitrogen leaching

Green et al. (2010) described the drainage and nitrogen (N) leaching results they obtained from an array of 45 manually sampled DFMs installed on a dairy farm near Lake Taupo in the center of the North Island of New Zealand. The soil is the free-draining Taupo sand, an Immature Orthic Pumice Soil. The pasture was rotationally grazed at about 3 cows per hectare, and received 4 split applications of urea each at $45 \text{ kg-N ha}^{-1} \text{y}^{-1}$. As expected for this winter-wet climate, most of the drainage occurred during the middle of the year (Fig. 6A). The average leaching loss on nitrate was around $40 \text{ kg ha}^{-1} \text{y}^{-1}$ over the 2 years (Fig. 6B). The variability in the individual nitrate measurements at any sampling time was large, as would be expected for pasture grazed by cows due

Fig. 5 A schematic of a passive tension fluxmeter. The fluxmeter is buried at the base of the rootzone, and drainage water enters the convergence rings by gravity and in response to capillary tension as a result of the 60 cm long fiberglass wick. The water then drips out via a tipping spoon that records the flow hydrograph, and it is then stored in the reservoir, awaiting removal of the leachate by a vacuum pump through the outlet tube that reaches up to the surface. Adapted from Green S, Deurer M, Clothier B, Andrews S, Cauldwell K, Roberts A, Wellwood M, and Thomas P (2010) Water and nitrogen movement under agricultural and horticultural land. Proceedings of the Workshop “Farming’s Future: Minimising footprints and maximising margins”. Fertiliser & Lime Research Centre, Massey University, 10–11 February 2010. [Farmed Landscapes Research Centre Paperlist10. (massey.ac.nz)].

the complex spatial patterns and timings of urinations and the depositions of dung. This highlights the value of low-cost devices like tension DFMs that mimic leaching processes at the local scale, yet enable sufficient replications to obtain representative data for the larger field scale.

Green et al. (2010) used the SPASMO (Soil Plant Atmosphere System Model) of Green et al. (2008) to simulate both the drainage and nitrate leaching through this free-draining pumice soil under this dairy pasture. These predictions are shown in Fig. 6 and well represent the N leaching processes.

Salt leaching

About one third of world’s land surface, some 50 million km², is either arid or semi-arid. These lands receive less than 400 mm of rain. Twenty percent of the world’s population, about 1.2 billion people, live in such arid, or semi-arid regions. Agricultural production in these regions is affected by soil salinity as the irrigation water used to grow the crops generally contains a mixture of naturally occurring salts (Ayers and Westcot, 1994). Inevitably then salts are added to the soil with each irrigation, whereas the plant roots only extract fresh water by osmosis. The extent to which salts build up in the soil depends on irrigation water salinity (EC_w , dS m⁻¹), irrigation management, and the adequacy of drainage to provide the leaching of salts (Wichelns, 2015). Leaching of salts can be achieved by applying an excess of irrigation water so that a fraction of the applied water drains through the rootzone carrying with it a portion of the accumulated salts. This excess water aliquot is known as the leaching fraction, LF , and is defined as

$$LF = \frac{\text{Depth of water leached below the rootzone}}{\text{Depth of irrigation water applied}}. \quad (12)$$

The goal of using a sufficient LF is to ensure that the soil-water salinity in the rootzone (EC_{sw}) does not reach a level above which losses in crop yield will occur. In the hyper-arid United Arab Emirates (UAE), Al Muaini et al. (2019) used an LF of 0.33 to irrigate date palms with water having an EC_w of 5 dS m⁻¹. Their measurements of EC_{sw} in the rootzone showed the diurnal cycling in

Fig. 6 Top (A): The time series of drainage from an array of 45 tension drainage fluxmeters (DFM) under rotationally grazed pasture on a dairy farm near Lake Taupo, New Zealand. Bottom (B): The time series of cumulative nitrate leaching as measured by the array of 45 DFMs. The red lines are modelled results using the Soil Plant Atmosphere System Model (SPASMO) of Green *et al.* (2008) taking into account the patches of dung and urine from the grazing animals. Adapted from Green S, Deurer M, Clothier B, Andrews S, Cauldwell K, Roberts A, Wellwood M, and Thomas P (2010) Water and nitrogen movement under agricultural and horticultural land. Proceedings of the Workshop “Farming’s Future: Minimising footprints and maximising margins”. Fertiliser & Lime Research Centre, Massey University, 10–11 February 2010. [Farmed Landscapes Research Centre Paperlist10. (massey.ac.nz)].

Fig. 7 The soil-water electrical conductivity EC_{sw} inferred from the measured water content (θ) and bulk soil electrical conductivity EC_b under a date palm irrigated with $5\ dS\ m^{-1}$ water (horizontal line). The irrigation regime, I , was chosen to provide a leaching fraction LF of 0.33. Two daily irrigations were carried out, one in the morning, and the other in the afternoon. There were no irrigations on Fridays (21 May, 28 May, and 4 June). Modified from Al Muaini A, Sallam O, Green SR, Kennedy L, Kemp P and Clothier BE (2019) The blue and grey water footprints of date production in the saline and hyper-arid deserts of the United Arab Emirates. *Irrigation Science* doi:10.1007/s00271-019-00642-6.

soil-water salinity with the build-up in EC_{sw} following the twice daily irrigations, and especially on Fridays when there were no irrigation (Fig. 7). This LF of one third was successful in leaching out the excess salts left after root-water extraction by the date palm roots, as there was no net build-up over time in the rootzone soil-water salinity.

Whereas this LF of one third was successful in maintaining a good rootzone EC_{sw} , the leaching of the excess salts in the drainage LF could pose a risk to the underlying aquifer. Ayers and Westcot (1994) showed that a simple mass-balance calculation estimates the salinity of the drainage water, EC_{dw} , to be

$$EC_{dw} = \frac{EC_w}{LF} \quad (13)$$

Thus with an LF at one third, the leachate salt-salinity in this case would be threefold that of the irrigation water, namely 15 dS m^{-1} . Over time, this higher salinity drainage water would likely find its way to the aquifer, and thereby increase the salinity of the underlying groundwater reserves.

Small, autonomous desalination plants are being increasingly used by farmers in arid regions to 'freshen-up' saline groundwater for use in irrigating high-value crops. This would seem to obviate the LF concerns raised above. Al Muaini et al. (2019) found the benefit cost ratio to be 1.4 if a small desalination unit was used to turn 15 dS m^{-1} groundwater into 5 dS m^{-1} water for irrigating date palms. This reduces the salt loading on the groundwater under crops now irrigated with fresher groundwater. However, there is then the problem of disposing of the reject brine from the desalination unit. Lyra et al. (2019) explored the feasibility, benefits, and risks of using the reject brine from desalination plants in an integrated land-based aquaculture system in conjunction with irrigation of a halophytic crop such as *Salicornia*. Current work seeks to understand better the long-term environment impact of salt leaching from such an Integrated Aquaculture Agriculture System (IAAS), and to develop improvements in food security and to enhance economic sustainability.

Modelling and risk assessment

Jarvis (1994) showed that despite the complicated mathematical forms of the coupled flow and transport Eqs. (3) and (4), and even (7) with (8), modern computers and efficient software schemes are easily able to solve them to predict the impact of land management on leaching processes. The results from models can then be used in risk-assessment frameworks to help us better understand the functioning of environmental systems, and to guide decisions for sustainable land management.

Initially, we provide some results from simplified modelling of the drainage processes under short pasture that is grazed, and a pine forest. A simple, lumped-parameter model (Green et al., 1999; Clothier et al., 2000) provides us with insight into the processes of leaching in terms of the controls on drainage quantity (D), and the contrast between the chemical concentration in the leachate (C), and total leachate load (M).

The simulations considered pasture and pines growing on soil typical of the Nelson region of New Zealand. Actual weather data from 1972 to 1998 were used. The maximum rooting depth, z_R , of 0.5 m was assumed for pasture, whereas the pine trees were considered able to root effectively to any prescribed depth. Simulations using a lumped parameter model were carried out for $z_R = 0.5, 1, 1.5, 2, 2.5$, and 3 m (Fig. 8).

When pasture and pines are grown on soils of a similar shallow depth of 0.5 m, the ET for the pines is lower due to sparseness of the canopy in the early stages of tree growth, and again following the thinnings. Nonetheless, due to interception losses by the trees reducing the effective rainfall, there is still a lower drainage quantity (D) under pines for such shallow soils. As the soil depth increases, the rise in ET restricts the drainage quantity (D) under the pines. For a shallow soil of $z_R = 0.5 \text{ m}$, the annual leachate load under pines is about 195 mm, or 20% of RF . When the soil is deep, say $z_R = 3 \text{ m}$, $D = 23 \text{ mm}$, or just 2.5% of RF . Thus the amount of water draining through soil is critically dependent on the nature of the vegetation cover and the soil's properties, and in particular the depth of effective rooting z_R .

Pasture production and pine tree growth were modelled through a nitrogen-balance scheme. Consequently, we could therefore also use this model to assess the risk posed to groundwater quality by the leaching of nitrate from the rootzone of these crops. We choose to present here, the average-annual nitrate-leaching concentrations, C , and the total annual loadings, M , for the pasture ($z_R = 0.5 \text{ m}$), and the pines with $z_R = 2 \text{ m}$ (Fig. 9).

There are two distinctive characteristics – the difference between the two land uses, and the skewed and non-Gaussian nature of the CPF's. The average concentration (probability 0.5) is much lower for pines (2.3 mg L^{-1}), than for pasture (12.1 mg L^{-1}), since a lot more of the nitrogen ends up stored in the plant tissue. Through the repeated grazings, and the additions of dung and urine, there are greater inputs of N into the pastoral system. The CPF for the trees is the most non-Gaussian, and this is due to the infrequent high loadings of nitrate that occur when, occasionally, a wet-year follows a dry year, and there is a surge in nitrate leaching. The simple, lumped-parameter model provides us with the amount of drainage (D) so that this can be multiplied by the nitrate concentration (C) to obtain a loading of nitrate of the receiving waters (M). The model results in Fig. 9 show that the loading on groundwater from grazed pasture is predicted to be $41 \text{ kg-N ha}^{-1} \text{ y}^{-1}$. However for the pine trees growing on this 2 m deep soil, the low concentrations of nitrate combined with the low amount of drainage, mean that there is simulated to be a very low leachate loading of just $0.6 \text{ kg-N ha}^{-1} \text{ y}^{-1}$. So whereas pine trees are predicted to have a negative impact on the quantity of drainage (D) reaching receiving water bodies, they are considered, by virtue of a lower total loading (M), to have a beneficial role in maintaining the quality of

Fig. 8 The influence of the depth of the rootzone on the amount of drainage (D) 'lost' by pine trees (open symbols) in comparison to pasture (closed symbols). Pasture is assumed to root to a maximum depth of z_R of 0.5 m, whereas the pines could extend their roots beyond 3.0 m, if soil depth permits. The mean annual rainfall over the 27 years was 974 mm. Reproduced with permission from Clothier BE et al. *Modelling Rootzone Processes: A Tool for Risk Assessment*. Water 2000. NZWWA.

Fig. 9 The predicted cumulative probability functions (CPF) of: (A) the concentration of nitrate in the leachate under pasture, and that under pine trees (soil depth 2 m, but the rooting depth for pasture $z_R = 0.5$ m, and pines $z_R = 2.0$ m). This CPF relates to the annualized value that was derived by running the model in daily time steps over 27 years, and summing the results to form annual totals, and (B) the total loading of nitrate on the receiving water bodies. Reproduced with permission from Clothier BE et al. *Modelling Rootzone Processes: A Tool for Risk Assessment*. Water 2000. NZWWA.

leachates moving to groundwaters. The interplay between land management and soil characteristics determine the quantity of drainage and the water quality of leaching.

Pesticide leaching

We continue with the use of the more-sophisticated modelling framework of SPASMO (Green et al., 2002) to predict the risks posed by the leaching of the active ingredient (AI) of three pesticides applied, in a simulation, to a grape vineyard on a Twyford silt loam located above an unconfined aquifer in Hawke's Bay, New Zealand. This framework can account, in a simple way, for the mobile-immobile partitioning of fast and slow-flow pathways of leaching through soil. The SPASMO simulations considered actively growing grape vines, and the grassed inter-row. The calculations were run on daily time-steps using a 27-year sequence of weather data (1972–1999) recorded from the local airport at Napier. The soil's physical and hydraulic properties were taken from the New Zealand Soils Database. Three herbicides, simazine, linuron and amitrole, were 'applied' at the label rates on the 15th September each year. This modelling of leaching predicts if, and how often, the soil-solution concentration at 3 m might exceed the Maximum Allowable Value (MAV) of 2 ppb of the AI.

Simazine, is quite mobile because of its low exchange with the soil's organic carbon (Eq. 6). Also it is persistent with a long degradation half-life of $t_{1/2} = 50$ days. Linuron is less mobile because of greater exchange with the soil's organic matter, and it is less persistent with $t_{1/2} = 33$ days. Amitrole is also less mobile because of low exchange, but it is much less persistent with $t_{1/2} = 3$ days. Therefore, concerning the likelihood of leaching to groundwater, we would expect the risks to be ranked simazine > linuron > amitrole. This expectation is borne out in the simulated leaching results, presented for a depth z of 3 m (Fig. 10). The average simazine concentration in the soil solution leaching through Twyford silt loam, over the 30-year period, is predicted to be just $0.03 \mu\text{g l}^{-1}$, although 10% of the time it will exceed $0.12 \mu\text{g l}^{-1}$, or 6% of MAV. Simazine should be used with greater caution, for it poses a greater leaching risk than either of the other two pesticides.

The risk of pesticide leaching also depends on the depth to groundwater. Fig. 11 shows the model results for linuron, as a function of depth. Here the data are presented as a cumulative probability function of exceedance. During the time taken to leach deeper into the soil profile, there will be degradation of the pesticide. For linuron, this means that there is predicted to be, on average (50% exceedance), about an order of magnitude drop in the concentration of active ingredient with every meter of soil depth. Even in the worst case of $z = 1$ m, the concentration of linuron will still be about an order of magnitude less than the MAV. Nonetheless, this analysis shows that shallow unconfined groundwaters are at the greatest risk of contamination from the leaching of surface-applied chemicals.

Fig. 10 Simulated herbicide concentrations in the soil solution at 3 m depth under grapevines growing on a Twyford silt loam. Each year, over 30 years, the herbicides were considered to be applied at the label rate, to 100% of the soil surface, in mid-September.

Fig. 11 The predicted probability distribution for the concentration of linuron in leachate at 3 depths under grapevines growing on a Twyford silt loam. Linuron was considered to be applied once each year, in mid-September, at the label rate of 1.0 kg ha^{-1} of active ingredient.

Upscaling

Whereas we are obtaining better measurements and improved modelling of local scale leaching processes, there is a challenge to upscale these to the field, farm and landscape scale. The inability to monitor or model at the larger spatial scale poses a problem for resource managers and regulators to develop practices and policies to protect the quality of both surface and subterranean water resources across whole catchments.

The first upscaling jump is to link rootzone leaching processes to those throughout the rest of the critical zone of the underlying vadose column of soil (Glaser et al., 2019), and the upper parts of the saturated region of the deeper aquifers (Banwart and Sparks, 2017). Gurevich et al. (2021) investigated the relationships between nitrogen measurements in the soil column, the groundwater monitoring-well scale (GW), plus the field and farm scale. They monitored in the rootzone (RZ) down to 3 m, the deep vadose zone (DVZ) down to 7 m, as well as the upper saturated zone (SZ) down to 14 m under a commercial almond orchard. Within the coarse-textured parts of the orchard, Gurevich et al. (2021) found that the measured RZ nitrate concentrations closely correlated with the GW concentrations underneath, indicating the significance of far-reaching and preferential flow paths. Overall, Gurevich et al. (2021) concluded that traditional soil-science RZ monitoring, through aggregated samples, could be extended to the DVZ, SZ and GW. The rider was, however, that about a dozen monitoring sites across the 56 ha orchard would be needed to assess GW nitrate impacts from land management practices on the surface.

Further spatial upscaling from the field and farm-scale to the whole catchment, with its complex mixing between surface and groundwaters, remains a major challenge, both to monitor and to model. The magnitude of this challenge is because, as Alexander et al. (2002) noted, there is a need to account "... for the variety of sources and removal processes and the nature of the interactions." They added that "... large quantities of nutrients are removed on the landscape and in the waterways, but the rates vary widely in response to such factors as climate, topography, soil, vegetation, and the physical and hydraulic properties of streams and reservoirs." Rivett et al. (2008) found that denitrification losses of nitrogen were more probable in confined aquifers and in the near-river environments of the riparian strip and the hyporheic zones. They listed eight areas of research where improved understanding would be required to enable mechanistic upscaling to the catchment scale.

Such complexity mitigates against the current usage of complex process-based or mechanistic models. Alexander et al. (2002) applied the SPARROW (Spatially Referenced Regression on Watershed Attributes) model of surface water-quality to estimate empirically the rates of nutrient delivery from both point and non-point sources to streams, rivers, and lakes. The catchment they studied was the 13,900 km² Waikato River Basin in Central New Zealand. There are 4 connected sub-catchments within this basin: Taupo, Waipa, Upper Waikato, and the Lower Waikato from which the Waikato River flows into the sea. The difference between the landscape yield of nutrients, and the watershed yield, is the attenuation. This represents the nutrients removed in streams and reservoirs. Across the four sub-catchments, Alexander et al. (2002) found nitrogen losses of 76% (Taupo), 42% (Upper Waikato), Waipa (39%) and 45% (Lower Waikato). The respective attenuations for phosphorus were found to be 89%, 59%, 53% and 51%. The Taupo sub-catchment is unusual because it is the least developed with forested land and Lake Taupo itself comprising over 50% of the catchment's area. These results highlight the complexity and the difficulty of upscaling leaching processes from the local scale, to the farm scale, right through to the catchment level.

Summary

The local leaching of chemicals through soil by percolating pore-water is the result of a complex of interconnected biophysical and biochemical processes. Firstly, biophysical mechanisms determine the quantity of water that quits the rootzone, destined for either groundwater or surface receiving waters. The prevailing weather, the nature of the vegetative cover, and the properties of the soil conspire to determine the amount of leachate. Secondly, the biochemical processes of exchange, production, and degradation control the concentration of chemical in the leaching solution.

It is imperative that better land-management practices be adopted to reduce the biochemical flows of nutrients, salts, and pesticides into receiving water bodies. Measurements and modelling will be critical in developing these new land-use practices. And soil and water monitoring across the landscape will be important for tracking progress to this goal of improving water-resource quality. At the local-scale, new measurement devices and mechanistic modelling are providing useful knowledge about leaching processes. However, there are challenges as to how these local measurements and predictions are upscaled to provide understanding at the field, farm, and catchment scale. New monitoring protocols and empirical models are helping in this quest.

Abstract

Colloid transport in porous media plays important roles in many agricultural, environmental, and engineering processes. Colloids vary in their source, composition, shape and structure but they all possess large specific surface areas and have high reactivity. Deposition or attachment, release or detachment, and straining are the processes controlling colloid transport in saturated media; attachment to air-water interfaces and the contact line, and film straining are additional processes affecting colloid transport through unsaturated media. The interactions of colloids with interfaces can be described by classical Derjaguin-Landau-Verwey-Overbeek (DLVO) theory, which considers van der Waals and electrical double layer forces and by extended DLVO, which includes non-DLVO forces (e.g., hydration, steric and hydrophobic). Current approaches to modeling colloid transport build on the classical colloid filtration theory. More complete mechanistic understanding of colloid retention and release processes and experimental validation will improve model development and our ability to manage both the risks and beneficial applications of environmental colloids.

Key points

- Colloid transport in porous media is relevant to multiple agricultural, environmental and engineering processes
- Deposition, release, and straining are the main processes controlling colloid transport in saturated porous media; retention at the air-water interface and contact line and film straining are additional processes affecting colloid transport in unsaturated media
- The Derjaguin-Landau-Verwey-Overbeek (DLVO) theory and extended DLVO theory are used for describing colloidal interactions
- Capillary force governs the interaction of colloids at the air-water interface and contact line
- Colloid filtration theory (CFT) is the theoretical basis for quantifying colloid transport in porous media under favorable conditions
- Surface roughness and charge heterogeneity play a critical role in colloid deposition and release under unfavorable conditions
- Mechanistic and continuum models are used to simulate colloid transport in porous media
- Upscaling from the pore-scale mechanistic calculations to predict colloid transport at continuum scales in natural media remains a challenge

Introduction

Colloids are particles in the size range of 1 nm to 10 μm . They are ubiquitous in subsurface porous media and can be generated in situ or introduced from external sources. Colloidal particles found in porous media like soil include inorganic (e.g., soil clay particles, oxyhydroxides of Fe and Al, carbonates, silica), organic (e.g., soil organic materials), engineered (e.g., manufactured nanoparticles), biological (e.g., bacteria and viruses) (McCarthy and McKay, 2004), and micro- and nanoplastics (Yu and Flury, 2021). Despite the differences in their source, composition and structure, colloids have two important properties in common: (1) they have very small sizes that give rise to large specific surface areas and high reactivity and (2) they can remain in suspension for long periods of time and therefore can potentially travel long distances in subsurface media. These properties are the key parameters controlling colloids' fate and transport in porous media (DeNovio et al., 2004).

Colloid transport in porous media has attracted intense research attention due to its relevance to agricultural and environmental concerns and important engineering processes such as membrane filtration and petroleum reservoir production. Early interests in colloid mobilization and transport in soil dates back to the 1930s, due to the important roles that colloids play in soil genesis and erosion and their influence on hydraulic conductivity in relation to irrigation management (Kretzschmar and Schafer, 2005). Classic colloid filtration theory (CFT) was developed in the 1970s for predicting the rate of particle removal in deep-bed filtration water treatment systems (Yao et al., 1971), which inspired more than four decades of active research on colloid retention and transport in porous media. Colloid-facilitated contaminant transport represents another intensely focused area of colloid research since the late 1980s as mobile colloids can serve as carriers of strongly sorbing substances (e.g., heavy metals, radionuclides, hydrocarbons, pesticides, nutrients) (McCarthy and Zachara, 1989). Research on the transport of biocolloids (e.g., bacteria and viruses), which is of significant relevance to various environmental and public health issues, including protection of drinking water supplies, in situ bioremediation, and riverbank filtration (Jin and Flury, 2002), attracted intense interests in the 1990s. Study of nanoparticles (NP), having one or more external dimensions in the range of 1–100 nm, represents a more recent focus in colloid research. Although NPs occur naturally and are ubiquitous in soil and water, engineered nanoparticles (ENPs) have been the center of most research to date because of their wide and varied use in many industrial and environmental applications and their potential impact on human health and ecological systems. There is an emerging interest in the role that soil colloids play in complexing and stabilizing soil organic carbon (OC) as well as the fate and transport of colloidal OC, especially in the context of global carbon cycling (Yan et al., 2018; Afsar et al., 2020).

Three major processes control the extent of colloid transport in porous media: deposition or attachment, release or detachment, and straining. Deposition involves transport from bulk fluid to the vicinity of a collector (e.g., soil mineral grain) surface and subsequent attachment on the surface. Straining describes the process of colloids being trapped in down-gradient pore throats that are too narrow to permit passage. Attachment and detachment are controlled by interaction forces (or energies) between colloids and collector surfaces (Ryan and Elimelech, 1996; Shen et al., 2020). The interaction forces/energies are quantitatively described by the standard and extended Derjaguin-Landau-Verwey-Overbeek (DLVO) theory, which are described in detail below.

Colloidal forces and interactions

DLVO forces

DLVO interaction force/energy is the sum of van der Waals (vdW) and electrostatic forces/energies and is expressed as a function of separation distance between interacting surfaces.

Van der Waals force/energy

The vdW force originates from quantum mechanics, acts between atoms, molecules and surfaces, and is composed of induction force, orientation force, and dispersion force. The Hamaker technique is the most commonly used to determine the vdW force/energy between two surfaces (Hamaker, 1937). This approach calculates the vdW energy (U_{vdW}) as sum of the interactions between colloids 1 and 2 in a vacuum as

$$U_{\text{vdW}} = \int_{V_1} \int_{V_2} u(h) q_1 q_2 dV_1 dV_2 \quad (1)$$

where q_1 and q_2 are molecules per unit volume, V_1 and V_2 are volumes of colloids 1 and 2, respectively, and h is the separation distance between the two particles. When the interaction bodies (e.g., a colloidal particle and a collector) are immersed in water, U_{vdW} between the colloid and collector surface is obtained using the following equation developed by Hamaker (1937):

$$U_{\text{vdW}} = U_{\text{PC}} + U_{\text{WW}} - U_{\text{PW}} - U_{\text{WC}} \quad (2)$$

where U_{PC} is U_{vdW} between the colloid and collector in vacuum, U_{WW} is U_{vdW} between the water colloid and the water collector in vacuum, U_{PW} is the U_{vdW} between the colloid and the water collector in vacuum, U_{WC} is the U_{vdW} between the water colloid and the collector in vacuum. The expressions used to calculate U_{PC} , U_{WW} , U_{PW} , and U_{WC} all have the form of $-A_{\text{PC}}f(h)$, $-A_{\text{WW}}f(h)$, $-A_{\text{PW}}f(h)$, and $-A_{\text{WC}}f(h)$, respectively, where $f(h)$ is a function determined by the geometrical configuration for an interaction (e.g., colloid size

and shape, separation distance). A_{PC} , A_{WW} , A_{PW} , A_{WC} are Hamaker constants for colloid-collector, water-water, colloid-water, and water-collector systems, respectively. Therefore, Eq. (2) can be rewritten as

$$U_{vdW} = -(A_{PC} + A_{WW} - A_{PW} - A_{WC})f(h) = -A_H f(h) \quad (3)$$

where A_H is the Hamaker constant for a colloid-water-collector system ($A_H = A_{PC} + A_{WW} - A_{PW} - A_{WC}$). The expression for calculating vdW interaction energy between a spherical colloid and flat surface is given by

$$U_{vdW} = -\frac{A_H}{6} \left[\frac{R}{h} + \frac{a}{h+2R} + \ln \left(\frac{h}{h+2R} \right) \right] \quad (4)$$

where R is the radius of a spherical colloid.

For more complex scenarios, such as interactions between hollow particles, between a colloid and a bubble, and between two air bubbles, modifications to Eqs. (1) and (2) can be made for calculating U_{vdW} for these interaction configurations (see Table 1). The expression for calculating U_{vdW} between a spherical particle and a flat air-water interface (AWI) is

$$U_{vdW} = -\frac{A_{WW} - A_{PW}}{6} \left[\frac{R}{h} + \frac{a}{h+2R} + \ln \left(\frac{h}{h+2R} \right) \right] \quad (5)$$

As the value of A_{WW} is generally smaller than A_{PW} , the Hamaker constant for the colloid-AWI interaction is negative and thus the vdW force is repulsive. The expression for calculating the vdW energy between a spherical particle and a spherical bubble is

$$U_{vdW} = -\frac{A_{WW} - A_{PW}}{12} \left[\frac{\gamma}{x^2 + xy + x} + \frac{\gamma}{x^2 + xy + x + y} + 2 \ln \left(\frac{x^2 + xy + x}{x^2 + xy + x + y} \right) \right] \quad (6)$$

where $x = \frac{H}{(R_1 + R_2)}$ and $\gamma = \frac{R_1}{R_2}$ (R_1 and R_2 are radii of the particle and bubble, respectively). The expression for calculating U_{vdW} between two spherical bubbles is given by

$$U_{vdW} = -\frac{A_{WW}}{12} \left[\frac{\gamma}{x^2 + xy + x} + \frac{\gamma}{x^2 + xy + x + y} + 2 \ln \left(\frac{x^2 + xy + x}{x^2 + xy + x + y} \right) \right] \quad (7)$$

The Hamaker approach assumes pairwise summation of vdW force/energy, which may be violated in condensed matter when many-body interactions and retardation effects are significant. An alternative approach to calculate U_{vdW} , the Lifshitz approach, avoids the pairwise summation assumption by ignoring the atomic structure and calculates the Hamaker constant by treating the interacting surfaces as continuous media with well-defined bulk properties such as their dielectric constants and refractive indices. However, this approach involves complex mathematical equations, so simplifications are necessary even for calculating simple interaction configurations (e.g., sphere-flat surface interaction). The simplified Lifshitz approach has the same expressions as the Hamaker approach for calculating vdW force/energy for simple interaction configurations and the only difference between the two approaches is the way to calculate the Hamaker constant.

Electrostatic or double layer force/energy

When a charged particle or collector surface is immersed in an electrolyte solution, an ionic cloud, also called an electrostatic double layer (DL), is formed around each surface. Overlap of the DLs results in DL energy/force when the particle approaches the collector surface. The Poisson-Boltzmann (PB) equation is used to determine the electrostatic potential distribution between a particle and a surface, and DL energy can then be obtained by analyzing the change in free energy of the DL system (Hogg et al., 1966). If the electrolyte is symmetric (i.e., when the cations and anions have the same valence), the PB equation is written as

$$\nabla^2 \Psi = \kappa^2 \sinh(\Psi) \quad (8)$$

where ∇^2 is the Laplacian operator, $\Psi (=ve\psi/kT)$ is reduced surface potential, v is charge number, e is electronic charge, ψ is electrostatic potential, k is the Boltzmann constant, T is absolute temperature, and κ is the inverse Debye screening length. The PB equation is nonlinear thus an analytical solution of electrical potential distribution does not exist even for a spherical particle. Accordingly, the PB equation has been frequently linearized (valid for small surface potentials, e.g., ≤ 25 mV) and given by

Table 1 Expressions used to calculate vdW energies between two interaction bodies in water.

Inter action configurations	Expressions
Colloid-collector	$U_{vdW} = U_{PC} + U_{WW} - U_{PW} - U_{WC}$
Colloid-AWI	$U_{vdW} = U_{WW} - U_{PW}$
Colloid-colloid	$U_{vdW} = U_{PP} + U_{WW} - 2U_{PW}$
Hollow colloid filled with water-collector	$U_{vdW}^{out} - U_{vdW}^n$
Hollow colloid filled with air-collector	$U_{vdW}^{out} - U_{vdW}^n + U_{WW}^n - U_{WC}^n$
Bubble-collector or colloid-AWI	$U_{WW} - U_{WC}$
Bubble-bubble	U_{WW}

$$\nabla^2 \Psi = \kappa^2 \Psi \quad (9)$$

Eq. (9) can be solved to obtain electrostatic potential at any point between the two interacting surfaces. Calculated electrostatic potential distribution can be adopted to calculate DL energy using the expression developed by Verwey and Overbeek (1948) and assuming appropriate boundary conditions, which include two extreme cases: constant surface potential and constant surface charge. However, the true condition lies somewhere between the two extremes. In addition to the two extreme conditions, linear superposition approximation (LSA) has also been used as a boundary condition (Shen et al., 2020). Analytical equations can be obtained, using the above three boundary conditions, to calculate DL energy per unit area between two parallel infinite planar surfaces (Table 2). Various analytical and numerical methods such as the Derjaguin approach (DA) and surface element integration (SEI) technique commence with these analytical equations to calculate DL energies between a colloid and a surface (Hogg et al., 1966; Bhattacharjee and Elimelech, 1997; Lin and Wiesner, 2010).

H is the separation distance, ϵ_0 is the dielectric permittivity in vacuum, ϵ is the relative dielectric permittivity of solvent, κ is the inverse Debye screening length, ν is the charge number, e is the electronic charge, ψ_1 and ψ_2 are the zeta potentials of two interacting surfaces, κ is Boltzmann constant, and T is absolute temperature, R is colloid radius.

Non-DLVO forces

In addition to the DLVO forces, non-DLVO forces are considered under certain circumstances. Hydration, steric repulsion, and hydrophobic interactions are three short-range repulsive forces that colloids commonly experience in saturated porous media. Hydration force F_{HR} , or hydration repulsion, occurs because it requires energy to dehydrate interacting surfaces that contain ionic or polar species, which is extremely significant and can inhibit colloids from approaching a collector surface at very short separation distances (i.e., < 0.5 – 0.6 nm, twice the thickness of a water molecule). However, hydration repulsion decays rapidly with separation distance in an exponential manner and is influenced by various factors including hydrophilicity of the interacting surfaces and solution ionic strength. Quantitative estimation of hydration energy remains difficult; thus only empirical models are available for determining F_{HR} . An example of the empirical models is

$$F_{HR} = \frac{E_0}{\lambda} \exp(-h/\lambda) \quad (10)$$

where λ is characteristic decay length, E_0 is the maximum repulsive energy per unit area at the closest possible separation distance, equal to $N_A C_h C_e \lambda$ (N_A is the Avogadro number, C_h is the proportionality constant defined as “hydration constant,” and C_e is the electrolyte concentration).

Steric repulsion results from interactions between surfaces with adsorbed chains and/or chain elements (e.g., surfactants, polymers, and organic matter) at short separation distances (i.e., less than twice the thickness of the adsorbed layer) (Ryan and Elimelech, 1996). At such short distances, the polymer chains on the two surfaces interdigitate and steric repulsion arises. In addition to interdigitation, the brushes are simultaneously compressed when the opposite polymer brushes contact each other. Therefore, both entropic and elastic effects contribute to steric repulsion. However, if some of the polymer chains on one

Table 2 Expressions for calculating DL energy for the interaction between two parallel infinite planar surfaces (E) and for the interaction between a spherical colloid and a planar surface using the DA technique (U_{DA}) or method of Lin and Wiesner (2010) (U_{LW}).

Boundary condition	Expressions
CSP	$E^{CSP}(H) = \frac{\epsilon_0 \epsilon \kappa}{2} \left[(\psi_1^2 + \psi_2^2) (1 - \coth(\kappa H)) + 2\psi_1 \psi_2 \operatorname{csch}(\kappa H) \right]$ $U_{DA}^{CSP}(H) = \pi \epsilon \epsilon_0 R \left[(\psi_1^2 + \psi_2^2) \ln(1 - \exp(-2\kappa H)) + 2\psi_1 \psi_2 \ln\left(\frac{1 + \exp(-\kappa H)}{1 - \exp(-\kappa H)}\right) \right]$ $U_{LW}^{CSP}(H) = [U_{DA}^{CSP}(H) + U_{DA}^{CSP}(H + 2R)] + [\beta^{CSP}(H) - \beta^{CSP}(H + 2R)]$ $\beta^{CSP}(x) = \frac{\pi}{\kappa} \epsilon \epsilon_0 \left[\frac{1}{2} (\psi_1^2 + \psi_2^2) \operatorname{Li}_2(\exp(-2\kappa x)) + 2\psi_1 \psi_2 [\operatorname{Li}_2(-\exp(-\kappa x)) - \operatorname{Li}_2(\exp(-\kappa x))] \right]$
CSC	$E^{CSC}(H) = 32 \epsilon \epsilon_0 \kappa \tanh\left(\frac{v\psi_1}{4kT}\right) \tanh\left(\frac{v\psi_2}{4kT}\right) \frac{(kT}{v\epsilon})^2 \exp(-\kappa H)$ $U_{DA}^{CSC}(H) = \pi \epsilon \epsilon_0 R \left[-(\psi_1^2 + \psi_2^2) \ln(1 - \exp(-2\kappa H)) + 2\psi_1 \psi_2 \ln\left(\frac{1 + \exp(-\kappa H)}{1 - \exp(-\kappa H)}\right) \right]$ $U_{LW}^{CSC}(H) = [U_{DA}^{CSC}(H) + U_{DA}^{CSC}(H + 2R)] + [\beta^{CSC}(H) - \beta^{CSC}(H + 2R)]$ $\beta^{CSC}(x) = \frac{\pi}{\kappa} \epsilon \epsilon_0 \left[-\frac{1}{2} (\psi_1^2 + \psi_2^2) \operatorname{Li}_2(\exp(-2\kappa x)) + 2\psi_1 \psi_2 [\operatorname{Li}_2(-\exp(-\kappa x)) - \operatorname{Li}_2(\exp(-\kappa x))] \right]$
LSA	$E^{LSA}(H) = \frac{\epsilon_0 \epsilon \kappa}{2} \left[-(\psi_1^2 + \psi_2^2) (1 - \coth(\kappa H)) + 2\psi_1 \psi_2 \operatorname{csch}(\kappa H) \right]$ $U_{DA}^{LSA}(H) = 64 \pi \epsilon \epsilon_0 R \left(\frac{kT}{v\epsilon} \right)^2 \tanh\left(\frac{v\psi_1}{4kT}\right) \tanh\left(\frac{v\psi_2}{4kT}\right) \exp(-\kappa H)$ $U_{LW}^{LSA}(H) = [U_{DA}^{LSA}(H) + U_{DA}^{LSA}(H + 2R)] + \frac{64 \pi \epsilon \epsilon_0}{\kappa} \left(\frac{kT}{v\epsilon} \right)^2 \tanh\left(\frac{v\psi_1}{4kT}\right) \tanh\left(\frac{v\psi_2}{4kT}\right) [-\exp(-\kappa H) + \exp(-\kappa(H + 2R))]$

CSP, constant surface potential; CSC, constant surface charge; LSA, linear superposition approximation.

surface are adsorbed on the other interacting surface, the polymers can draw the surfaces closer to each other, causing attractive bridging forces. In this case, the repulsive steric and attracting bridging forces can exist simultaneously and have coupled but non-additive effects on the interaction of the surfaces.

Hydrophobic interaction involves the configurational rearrangement of water molecules as two hydrophobic surfaces come together, particularly common when AWI, which is superhydrophobic, is involved. Although hydrophobic interaction has long been believed to be due to a "hydrophobic bond," this interaction has later been recognized to act at a longer range than a typical covalent bond. Israelachvili and Pashley (1982) were the first to directly measure the forces between two hydrophobic surfaces in aqueous solution. They found that hydrophobic force decayed exponentially with separation distance with a characteristic length of ~ 1 nm. The origin of hydrophobic interaction is not completely known but has been suggested to include bridging of surface nano-/micro-bubbles, bubble cavitation during surface approaching or separation, or entropy elevation during the disruption and change of hydrogen bonding network at the water-hydrophobic interface.

Under unsaturated conditions, colloids can interact with AWI, and such interactions largely depend on colloid charge and hydrophobicity. If interactions are attractive, the thin water film between colloids and AWI breaks, and colloids experience capillary forces when they penetrate the AWI. The capillary force arises due to change in the shape of the AWI upon contacts with colloids and corresponding actions of surface tension force and Laplace pressure (Flury and Aramrak, 2017). The magnitude of capillary forces is typically much larger than the DLVO interaction forces (Gao et al., 2008), so they can play a significant role in the aggregation, retention and release of colloids in unsaturated media. Calculations of the capillary force require solving the Laplace equation of capillarity and determining the meniscus profile around the colloids with different configurations (Flury and Aramrak, 2017).

In a porous medium with low water content, a capillary meniscus is formed due to capillary force, which leads to pinning of a colloid to the stationary solid surface (Fig. 1A). In this case, the capillary force (F_{cap}) normal to the AWI can be calculated by

$$F_{cap} = \pi R \gamma [2 \sin \phi \sin(\theta + \phi) + \cos \theta (1 + \cos \phi)^2] - \sin \phi \quad (11)$$

where γ is surface tension of water, θ is contact angle, and ϕ is filling angle. As water content in the porous medium increases, the adsorbed water film expands, resulting in a free water surface (Fig. 1B). The capillary force can be determined

$$F_{cap} = \pi R^2 \rho g \left\{ \frac{Hc + Rc[1 + \cos(\pi - \phi)]}{Rc} + \frac{2}{(Rc)^2} \sin(\phi + \theta) \sin \phi \right\} \quad (12)$$

where g is gravitational acceleration, H is thickness of the free water film, $c = \sqrt{(\Delta \rho g)/\gamma}$ is the capillary number and $\Delta \rho$ is the difference between water and air density. The thickness of H is related to the filling angle ϕ , and their relationship is described by the Laplace equation. When the water film thickness H is larger than the colloid diameter by further increase of water content (Fig. 1C), the direction of the capillary force changes and become opposite to the adhesive force between the colloid and solid surface. The maximum capillary force in the opposite direction (F_{det}) can be estimated

$$F_{det} = 2\pi R \gamma \sin^2 \left(\frac{\theta}{2} \right) \quad (13)$$

The DA and SEI technique

The DA and SEI techniques are the two most commonly used methods for interaction energy calculations, which are based on analytical equations of differential interaction energies between two planar surfaces per unit area or between an area element and an infinite planar surface, as described previously. The DA technique calculates sphere-sphere interaction energy by discretizing sphere surfaces into infinitesimally ring-shaped flat plates and then sums up differential interaction energies between each pair of ring plates (e.g., dS_1 and dS_2 in Fig. 2A). The differential interaction energies between the ring plates are calculated using the expressions shown in Table 2. Calculations using the DA technique are accurate only for large colloids and when $\kappa R > 5$ (κ is the inverse Debye screening length). The SEI technique calculates the interaction energy for a sphere-flat interaction (Fig. 2B), developed by Bhattacharjee and Elimelech (1997). In this case, the sphere is discretized into small elements, and the total interaction energy is the sum of differential interaction energies between each area element and the planar surface. The SEI technique has overcome the limitations of DA and can accurately calculate interaction energies even for nano-sized particles and at all possible separation distances.

DLVO interaction energy/force profiles and maps

DLVO interaction energy profile is used for interpreting attachment and detachment of colloids on/from surfaces. A standard DLVO interaction energy profile is constructed by plotting total interaction energy (e.g., sum of vdW and DL energy) as a function of separation distance between a colloid and a collector surface. When a colloid and surface are like-charged, the electrical DL energy is repulsive and the combination of the repulsive DL energy with the attractive vdW energy results in an infinitely deep primary energy well, called the primary minimum, at a small separation distance, a maximum energy barrier, and a shallow attractive energy well, called the secondary minimum, at a larger distance. Therefore, the classic DLVO theory predicts that colloids are irreversibly attached at the deep primary minima with infinite depths.

Fig. 1 Capillary forces acting on a colloid for different configurations of the AWI. (A) capillary meniscus for a dry porous medium with adsorbed water film, (B) free water film with thickness H smaller than the colloid diameter $2R$ ($H < 2R$), (C) water film thickness expanded to $H > 2R$, and (D) further expansion of water film thickness leads to detachment of colloid from solid surface. Figure and caption from Flury M and Aramrak S (2017) Role of air-water interfaces in colloid transport in porous media: A review. *Water Resources Research* 53: 5247–5257, <https://doi.org/10.1002/2017WR020597>, with permission.

Predictions by the classic DLVO theory is often found to be in contrast to observations from many column experiments, which show that colloids attached at primary minima can be released by reducing solution ionic strength and by increasing hydrodynamic shear (Ryan and Elimelech, 1996; Shen et al., 2020). Surface force measurements in microscopic experiments unambiguously showed the existence of very strong short-range repulsion at separation distances less than a few nanometers. This is likely due to the existence of the non-DLVO forces such as hydration and hydrophobic interactions, as previously discussed. To date, only empirical expressions are available to estimate these short-range interaction forces. Alternatively, the effect of short-range repulsion is included by designating a minimum separation distance corresponding to shear plane distance and the thickness of hydration layers between surfaces and by calculating Born potential energy (Ryan and Elimelech, 1996). The depth of primary minimum becomes limited when the aforementioned short-range repulsions are involved (Fig. 3). Colloids can overcome the energy barriers to attach at the

Fig. 2 Schematic of interaction between two spherical particles or between a spherical particle and a flat plate. dS_1 and dA are differential area elements on colloid and collector surfaces, respectively, h is local distance between the elements dS_1 and dS_2 or between dS and dA , n_1 and n_2 are unit outwards normal to the particle and collector surfaces, respectively, k_1 and k_2 are unit vectors directed towards the positive and negative z axis, respectively, H is separation distance. Modified from Shen C, Jin Y, Zhuang J, Li T, and Xing B (2020) Role and importance of surface heterogeneities in transport of particles in saturated porous media. *Critical Reviews in Environmental Science and Technology* 50: 244–329, with permission.

Fig. 3 DLVO interaction energy U_T as a function of separation distance. For the red curve, a primary minimum, maximum energy barrier, and a secondary minimum is present; In black curve, only a primary minimum is present; In blue curve, the interaction energy decreases monotonically with increasing separation distance. Modified from Shen C, Jin Y, Zhuang J, Li T, and Xing B (2020) Role and importance of surface heterogeneities in transport of particles in saturated porous media. *Critical Reviews in Environmental Science and Technology* 50: 244–329, with permission.

primary minima if the energy barriers are small and the adhesive torques acting on the colloids at the primary minima are larger than applied torques (e.g., hydrodynamic torque). Colloids may also attach at the secondary minima if the secondary energy wells are deep enough to prevent the colloids from being released by hydrodynamic shear. Colloid attachment in the presence of repulsive energy barriers is termed “unfavorable”, which is the most prevalent condition in natural porous media where colloids and collector surfaces are like charged. When colloid and collector surfaces are oppositely charged, both the DL and $\mathcal{W}$ energies are attractive and only the primary minimum exists in the interaction energy profile. In this case, colloids nearby a collector surface will attach at the primary minima as the attraction and the attachment is “favorable”.

A DLVO interaction energy profile/curve is sufficient to characterize the interactions between a particle and a collector surface in the absence of surface heterogeneity (Fig. 4A). However, if physical and chemical heterogeneities exist on the collector surface, the interaction energy profile changes with the horizontal location of the colloid (Fig. 4B). Shen et al. (2020) showed that the interaction energy can decrease monotonically with separation distance at low ionic strength values when nanoscale protruding asperities exist on the collector surface (Fig. 3). This happens when colloids experience repulsion at all separation distances, thus there are no energy wells available for attachment. Notably, to describe the variation of interaction energy with the horizontal position due to surface heterogeneities, DLVO interaction energy maps can be constructed by computing interaction energies at a given separation distance and over a range of locations (x, y). Shen et al. (2012) presented DLVO interaction energy and force maps in the xz or yz plane by changing the vertical positions (x, z) or (y, z) in a rasterized manner (Fig. 5). The DLVO interaction energy and force maps in xz or yz plane have the advantage of clearly showing variations of the primary minimum, energy barrier, and secondary minimum due to the influence of surface heterogeneity.

Processes governing colloid transport

Fig. 6 provides a schematic of major locations and mechanisms for colloid retention in saturated (Fig. 6A) and unsaturated (Fig. 6B) porous media. Colloid transport in saturated porous media is controlled by deposition at the solid-water interface (SWI) and straining (Bradford et al., 2006; Shen et al., 2020). While colloid retention at SWI and straining occur in both saturated and unsaturated media, there are two major complications in the unsaturated porous media: the presence of an air phase and transient

Fig. 4 Illustration of a colloid interacting with a (A) homogeneous or (B) heterogeneous surface.

Fig. 5 DLVO interaction energy maps in xz or xy plane. R is colloid radius. The scale bar between the plots represents the interaction energy in units of kT (k is Boltzmann constant and T is absolute temperature). Modified from Shen C, Wang F, Li B, Jin Y, Wang L-P, and Huang Y (2012) Application of DLVO energy map to evaluate interactions between spherical colloids and rough surfaces. *Langmuir* 28: 14681–14692, with permission.

Fig. 6 Schematic of colloid retention mechanisms in (A) saturated and (B) unsaturated porous media. (A) Major colloid retention mechanisms in saturated porous media are retention at the solid-water interface (SWI) and straining. (B) Additional colloid retention mechanisms in unsaturated porous media include film straining and retention at the air-water interface (AWI) and contact line.

flow events (McCarthy and McKay, 2004). The presence of air phase affects colloid partitioning and distribution between the phases and results in additional mechanisms of colloid retention including retention at the air-water-solid interface (contact line) and the AWI, and by film straining (e.g., Bradford et al., 2006).

Deposition

Deposition is a process that involves collision of a colloid in bulk solution with a collector surface and subsequent immobilization at the surface. According to the CFT, deposition is controlled by three individual retention mechanisms: diffusion, interception and sedimentation (Yao et al., 1971). Deposition is quantitatively represented by the single collector removal efficiency η in the CFT, which is defined as the ratio of the overall colloid deposition rate onto a collector to convective transport of upstream colloids toward a collector (Ryan and Elimelech, 1996). The single collector removal efficiency can be obtained by solving the convective-diffusion equation, taking into account the aforementioned three deposition mechanisms or by quantifying the trajectory of particles, using the Lagrangian method in both cases.

Existing theoretical calculations of deposition rate or single collector removal efficiency can be orders of magnitude smaller than experimental observations under unfavorable conditions, thus they cannot accurately predict colloid transport in porous media (Molnar et al., 2015; Shen et al., 2020). Consequently, an additional factor, the attachment efficiency α , is used in the CFT to account for the discrepancies. The single collector removal efficiency η is decoupled as the product of single collector contact efficiency η_0 , which quantifies the transport step from bulk solution to the vicinity of a collector surface, and the attachment efficiency α , which quantifies the attachment step. Various correlation equations have been developed by regressing dimensionless parameters governing colloid deposition against the theoretical single collector contact efficiency value over a broad range of parameter values (Yao et al., 1971; Rajagopalan and Tien, 1976; Tufenkji and Elimelech, 2004), and a summary of the correlation equations can be found in Molnar et al. (2015) and Shen et al. (2020).

The attachment efficiency α represents the fraction of collisions with the collector surface that results in attachment, which is determined by conducting column experiments and calculated using the following expression

$$\alpha = -\frac{2}{3} \frac{d_c}{(1-f)L\eta} \ln(C/C_0) \quad (14)$$

where d_c is collector diameter, f is porosity of a porous medium, L is column length, C and C_0 are colloid concentration of influent and effluent suspensions, respectively. Numerous theoretical expressions have also been developed to calculate the attachment efficiency. For example, the Boltzmann model is used to calculate the attachment efficiency at primary minima

$$\alpha = \exp(-U_{\max}) \quad (15)$$

where $U_{\max}$ is the maximum energy barrier.

Attachment efficiency at secondary minima can be calculated using the Maxwell equation (Hahn et al., 2004) and a number of empirical correlations (Shen et al., 2020). Although deposition at secondary minima has been a subject under debate since the development of DLVO theory, experimental evidence using techniques, such as total internal reflection microscopy, has provided unambiguous support for its occurrence (Shen et al., 2020).

Release

Deposition is reversible from the primary minimum under certain conditions, including when short-range repulsion reduces the depth of the primary minimum and when hydrodynamic torques exceed the adhesive torques at high flow velocities. Torque balance analysis can be used to determine the release from primary minima; rolling has been found to be the governing mechanism

causing the release of colloids from primary minima compared to lifting and sliding (Bergendahl and Grasso, 2000). Additional mechanisms that can cause colloid release from primary minima include: presence of nanoscale surface protruding asperities, which can significantly reduce the primary minimum depth at low ionic strength, and increased electrostatic repulsion and steric repulsion by increasing pH or introducing surfactants (e.g., polymers and natural organic matter). Colloids can even spontaneously detach from primary minima by Brownian diffusion if the primary minimum depths are reduced to be comparable to the average kinetic energy of a colloid ($1.5 kT$, k is Boltzmann constant and T is absolute temperature).

Colloids that are attached via secondary minimum association are more readily released compared to those attached at primary minima. They can be released by decreasing solution ionic strength because this decreases the depths of secondary minima (Hahn et al., 2004). These colloids may also translate and rotate along the collector surfaces due to hydrodynamic shear when the collector surfaces are relatively smooth. However, deposition in deep secondary minima is stable when hydrodynamic shear is absent (e.g., at stagnation point regions), or when tangential attractive forces exist (e.g., presence of nanoscale protruding asperities).

Straining

Straining refers to the retention of colloids in down-gradient pore throats, formed due to intersection of at least two interfaces that are too small for the colloids to pass through. Straining mainly occurs at the interaction of only two solid-water interfaces, termed grain-grain contact or wedging. Straining is controlled by the size of colloids and pore size distribution of a porous medium and can be influenced by chemical factors such as solution ionic strength and surface tension (Bradford et al., 2006). In contrast to deposition that causes exponential retention profiles under favorable conditions, colloids retained via straining are mainly distributed at the inlet of a porous medium, resulting in hyperexponential retention profiles.

Retention at AWI, contact line and film straining

AWI plays a critical role in colloid transport in porous media, and can both reduce and enhance transport depending on various factors (Flury and Aramrak, 2017). The processes and mechanisms controlling colloid retention at the AWI and contact line depend on the configuration of air phase (e.g., as a continuous phase or trapped air bubbles) and corresponding hydrodynamic regime. Two hydrodynamic regimes are typically considered: steady-state and transient, under which the roles that the AWI plays in colloid transport can be remarkably different.

Steady-state regime represents flow under constant saturation (water content) and flow rate. Under this regime, air is trapped in porous media, AWI boundaries remain reasonably constant, and therefore the AWI and contact line can be considered stationary. Under steady-state conditions, there is more colloid retention in unsaturated porous media compared to saturated ones at the same colloid and solution chemistries (DeNovio et al., 2004), which increases with decreasing water content (e.g., Wan and Tokunaga, 1997). The increased retention has been attributed to retention at the AWI and on the contact line and to film straining.

Interaction of a colloidal particle with AWI is governed by forces including the repulsive vdW force, electrostatic interaction, and hydrophobic force. Capillary force, which has been described previously, acts on colloids only after they penetrate and attach to the AWI. The majority of the colloids found in the environment are hydrophilic and negatively charged, thus the net interaction force between colloids and AWI is either repulsive or weakly attractive (due to hydrophobic force). Under such conditions, AWI does not serve as a major retention site for colloid attachment from the bulk solution. The net interaction force may be different for positively charged colloids so the role of AWI needs to be considered for individual cases.

Under steady-state conditions, contact line is stationary and colloid motion towards the contact line is determined by the flow field in the bulk solution. When colloid motion is parallel to contact line, colloids can be retained in the contact line regions at locations with low or zero flow velocities. Colloids can also be carried to the contact line by convective flows, Brownian motion, or evaporation and be retained via so-called film straining (Wan and Tokunaga, 1997). In unsaturated porous media where water is present in the form of pendular rings around grain-to-grain contacts and thin films on grain surfaces, retention can occur both within disconnected pendular rings and in thin films for colloids with sizes comparable to or smaller than the thickness of the thin films. These colloids can be re-mobilized back into bulk solution upon a transient event (infiltration). In general, colloids can be retained on the contact line with or without penetrating AWI (Flury and Aramrak, 2017). Fig. 7A illustrates colloid retained both at the AWI and the contact line and the role of capillary force. Alternatively, colloids can be trapped within the liquid wedge on the contact line (Fig. 7B). In this case, the thin film around the particle doesn't break; the theoretical treatment of such retention was proposed by Gao et al. (2008).

Transient flow regime in unsaturated porous media includes such events as imbibition (infiltration), drainage, and evaporation. Transient flow has been recognized as the main process governing colloid mobilization in soil, which is driven by multiple mechanisms including thin-film expansion, mobilization with moving AWI or contact line, and hydrodynamic shear (Aramrak et al., 2011; DeNovio et al., 2004). During transient flow, the moving AWI and contact line can mobilize colloids and transport them with the moving AWI. There are a number of forces acting on an attached colloid upon its interaction with a moving contact line, and the force balance determines whether a colloid is mobilized or remains on the surface (Fig. 8). These forces include adhesion (DLVO) force between the attached colloid and solid collector surface, hydrodynamic force, and capillary force. Capillary force is the governing force of colloid mobilization, and its magnitude and direction determine whether a colloid is mobilized or pinned against the collector surface (Lazouskaya et al., 2013). Therefore, colloid and collector contact angles and surface tension are the parameters that affect the capillary force value and colloid mobilization. Once removed from the collector surface by the capillary force, colloids remain attached at AWI and can be further transported with the moving AWI.

Modified from Lazouskaya V, Wang LP, Or D, Wang G, Caplan JL, and Jin Y (2013) Colloid mobilization by fluid displacement fronts in channels. *Journal of Colloid and Interface Science* 406: 44–50, doi: 10.1016/j.jcis.2013.05.078, with permission.

Colloid mobilization mechanisms of model spherical colloids during imbibition and drainage in porous media are relatively well understood (Lazouskaya et al., 2013). However, mobilization of natural colloids in soil is more complex and can vary depending on soil properties (composition, organic matter content) and other parameters such as moisture content, duration and history of AWI transients, and evaporation. Overall, transient conditions (either chemical or physical such as ionic strength or flow rate) are favorable for colloid mobilization. Additionally, water loss with drainage and evaporation induces capillary stresses and weakens soil capillary walls, which increases the number of mobilized colloids with subsequent infiltration events, and drying duration accentuates these effects (e.g., Michel et al., 2010). Freezing/thawing cycles mobilize even more colloids than wetting/drying events due to the additional mechanical stresses on soil structural units (Flury and Aramrak, 2017).

Experimental approaches

Colloid transport is determined by the relative magnitudes of concurrent processes of retention (deposition, straining) and release or mobilization (Sen and Khilar, 2006). Laboratory methods to study and quantify colloid retention and release in natural and

model porous media include batch and column experiments, pore-scale studies using microscopy, X-ray tomography and other advanced tools. These methods focus on different processes and they are often used to complement each other.

Similar to studying chemical sorption, batch experiments are conducted to measure attachment and detachment of colloids to and from solids (e.g., sand or soil). In typical batch experiments, a solution containing a known concentration of colloids is added to a known quantity of sand/soil at a predetermined solid-to-liquid mass ratio. The mixture is then shaken on a rotary table or a shaker at a specified rotation speed for a specified amount of time to reach (apparent) equilibrium. The final or equilibrium concentration of colloids in solution is measured and the amount of attached colloids is calculated based on the mass balance, which is then used to construct equilibrium isotherms using linear, Langmuir or Freundlich models. The colloid attachment process is typically considered as linear and reversible and a distribution coefficient (K_D) is obtained and used to calculate a retardation factor that can be used in transport models (Schijven and Hassanizadeh, 2000). In this manner, important parameters such as colloid attachment and detachment can be measured under various chemical conditions (e.g., solution pH and ionic strength). The main advantages of batch experiments are their simplicity and being less labor-intensive compared to column and field studies.

Laboratory column experiments under saturated or unsaturated porous media dominate colloid transport research. The experimental setup includes packing a column with porous media at desired water saturation, followed by introducing influent colloid suspension. The effluent is collected and analyzed for colloid concentration, and the results are used to generate breakthrough curves. Column experiments can be conducted at steady state or transient state (DeNovio et al., 2004). Although results from batch and column experiments often cannot be compared directly due to different solid-to-solution ratios and other interaction conditions, parameters from batch experiments (e.g., attachment and detachment coefficients) are sometimes used to aid interpretation of results from column experiments (Bradford et al., 2006). Although column experiments provide valuable data in colloid transport, mechanistic understanding is hindered by the combined effects of multiple processes that occur simultaneously in columns.

With the progress in microscopy, it became possible to distinguish colloid retention mechanisms and their contributions to colloid transport by conducting pore-scale and meso-scale visualization experiments (Ochiai et al., 2006). These experiments complement column experiments and generate important insights into colloid retention mechanisms especially in unsaturated systems. Typical pore-scale experiments include a micromodel device (e.g., etched glass and silicon pore networks, media-packed flow cells, and capillary channels) connected to a syringe pump and visualized with a microscope (Lazouskaya et al., 2006, 2011, 2013). Various micromodel designs represent different pore and AWI configurations. AWI can be introduced as entrapped air bubbles, as a free surface in open capillaries and packed media, and as phase boundary in two-phase flows. Similar to column experiments, pore-scale experiments can be carried out to study colloid behavior during both steady-state and transient flow processes. Analysis of these configurations and corresponding results clarified how the roles of AWI and contact line in colloid retention and mobilization differ in steady-state systems with stationary AWI and contact line and in the systems with moving AWI and contact line (e.g., two-phase flow) (Flury and Aramrak, 2017). The common limitations of pore-scale experiments include the small representative area of study and the two-dimensional nature of such systems. Fig. 9 illustrates fluorescent colloids and a moving AWI during imbibition and drainage in a microfluidic channel with a trapezoidal cross section. Because the channel depth was only 20 μm , colloid retention at AWI and on the contact line could be clearly distinguished.

Imaging studies at the intermediate meso-scale provide the means to investigate the pore structure and topography of a porous medium, configurations of water films and entrapped air, and colloid retention in three-dimensional domains. These studies employ advanced imaging techniques such as magnetic resonance imaging, X-ray and neutron tomography, and light-based

Fig. 9 Images of microfluidic channel acquired with the confocal microscope and the schematic cross-sections in two regimes: (A) imbibition and (B) drainage. The dashed lines mark the approximate location of the schematic cross-sections. Modified from Lazouskaya V, Wang L, Gao H, Shi X, Czymbek K, and Jin Y (2011) Pore-scale investigation of colloid retention and mobilization in the presence of a moving air–water interface. *Vadose Zone Journal* 10: 1250–1260, doi:10.2136/vzj2011.0003, with permission.

microscopy methods (Ochiai et al., 2006). Compared to pore-scale experiments, the drawback of these methods is the lower resolution. Consequently, at this scale the studies involved either large particles (e.g., $\sim 5\ \mu\text{m}$, $36\ \mu\text{m}$) or colloidal aggregates (Ochiai et al., 2006).

Field studies of colloid transport are scarce, due to the difficulty in conducting well-controlled experiments in undisturbed soil and potential artifacts related to experimental procedures. Experiments at the field scale typically focus on colloid mobilization or breakthrough measurements in soil lysimeters. Several field studies have attributed the peaks in measured colloid concentration to passage of moving AWIs during infiltration and drainage events (DeNovio et al., 2004; Flury and Aramrak, 2017). Other parameters that affect colloid mobilization in field experiments include changes in solution chemistry (e.g., ionic strength and pH) and hydrodynamic shear stress. In addition to colloid mobilization, field studies on colloid-facilitated transport of contaminants have also been conducted (Sen and Khilar, 2006). However, more field-scale studies are needed in all areas of colloid transport including colloid, biocolloid, micro/nanoplastics, and colloid-facilitated transport.

Factors influencing colloid transport

All factors that govern the processes of colloid deposition and release affect colloid transport in porous media. They include properties of colloids and porous media, solution chemistry (e.g., composition, pH and ionic strength), and hydrodynamics (water content and flow velocity). The effects of these parameters have been studied and documented extensively (Ryan and Elimelech, 1996; Flury and Aramrak, 2017; Shen et al., 2020). Thus, the sections below only cover the factors that have been the focus in more recent studies.

Surface roughness and charge heterogeneity

Colloids of environmental relevance have rough surfaces, thus their behavior in natural environments deviates from predictions by standard theories developed based on colloids with ideal smooth surfaces. Nanoscale protruding asperities act to reduce local repulsive energy barriers thus increase colloid deposition in primary minima under unfavorable conditions. On the other hand, the protruding asperities reduce the depths of primary minima, and accordingly colloids deposited atop the protruding asperities are more readily released by reducing solution ionic strength or increasing flow velocity, leading to reduced colloid deposition in primary minima under favorable conditions (Bizmark et al., 2020). In addition, colloids are favorably deposited at secondary minima when solution ionic strength is low and the secondary minimum wells are enhanced at concave asperities (Shen et al., 2020). Colloids can also deposit at the primary minima in the area close to the vertex of the concave surfaces where the repulsive energy barriers are reduced or even disappear (Fig. 10). Colloid deposition at primary minima at concave locations is irreversible when solution ionic strength is reduced because the primary minimum depth is deep at all ionic strength values (Li et al., 2017).

Surface chemical heterogeneity can also reduce repulsive energy barriers and increase colloid deposition in primary minima under unfavorable conditions. In addition, chemical heterogeneity increases primary minimum depth and thus adhesion, which makes colloid deposition in primary minima less reversible (Shen et al., 2020). For macroscale chemical heterogeneity, the

Fig. 10 (A) A scanning electron microscope (SEM) image illustrating the irreversible deposition of colloids at concave sand surface; (B) A DLVO interaction force map showing the absence of energy barrier at the vertex of a concave surface due to intersecting of two half planar surfaces. Figures from Li T, Jin Y, Huang Y, Li B, and Shen C (2017) Observed dependence of colloid detachment on the concentration of initially attached colloids and collector surface heterogeneity in porous media. *Environmental Science & Technology* 51: 2811–2820, with permission.

attachment efficiency is proportional to the fraction of heterogeneity and can be quantified by the patchwise model (Johnson et al., 1996). However, when both micro- and nano-sized chemical heterogeneities are present, the model by Pazmino et al. (2014), which uses trajectory analysis and takes into account torque balance, can be used.

Colloid shape

Colloids are highly variable in shape (e.g., plate-like clays, rod-like goethite and bacteria, thin-wire like carbon nanotubes). The current knowledge on colloid transport in porous media is primarily based on studies that used spherical colloids as models, whereas only few studies have looked at the effect of shape exclusively (Liu et al., 2010; Aramrak et al., 2013). Results from several studies conducted under saturated conditions are not consistent, ranging from enhanced, reduced, and similar retention of rod-shaped colloids compared to spherical colloids (e.g., Ma et al., 2020), which are likely due to the coupled effects of colloid shape, hydrodynamics, and physicochemical properties of colloid and collector surfaces. Non-spherical colloids have different translational and rotational trajectories due to flow field and Brownian motion compared to spherical colloids. Under unsaturated conditions, the presence of AWI and contact line can further alter transport behavior of non-spherical colloids. For example, capillary forces are stronger for particles with edges compared to smooth spherical particles (Flury and Aramrak, 2017).

Modeling colloid transport

Equilibrium adsorption and kinetic deposition

The CFT considers colloid deposition as a first-order kinetic and irreversible process but does not consider deposition at secondary minima (Ryan and Elimelech, 1996). This approach is inadequate for quantifying colloid transport in natural porous media where interactions of colloids and medium surfaces occur under mostly unfavorable conditions where deposition at secondary minima is an important mechanism. New advances include combining equilibrium adsorption equations (e.g., linear isotherm and Langmuir model) and kinetic interaction into the convection-diffusion equation to simulate colloid transport in porous media. In some cases, using an equilibrium adsorption model is warranted for simulating colloid deposition. For example, the presence of nanoscale protruding asperities can cause shallow primary energy wells and thermodynamic equilibrium may establish between the tips of nanoscale protruding asperities and bulk solutions.

Blocking and ripening

Blocking refers to the phenomenon that colloids, previously attached on a collector surface, inhibit subsequent attachment of approaching colloids in their vicinity. Blocking occurs when interactions between the attached and approaching colloids are unfavorable. Blocking can be quantified by conducting column experiments to measure the value of C/C_0 at the plateau of breakthrough curves. The Langmuir approach is most frequently used to describe colloid blocking as

$$\omega = \frac{S_{max} - S}{S_{max}} \quad (16)$$

where ω is fraction of porous medium available for deposition, S_{max} is colloid retention capacity, S is colloid concentration on the solid phase of a porous media. The use of Langmuir function to simulate the blocking process has been debated because it displays a linear dependence on fractional surface coverage while microscopic examinations have shown that nonlinear relationship exists when surface coverage is high (Shen et al., 2020). Alternatively, the random sequential adsorption (RSA) model has been adopted to account for the nonlinear blocking effects. The classic RSA model delineates irreversible deposition of hard spherical colloids on a homogeneous surface in a monolayer, which is written as

$$\omega = 1 + a_1 \left(\frac{S}{S_{max}} \right) + a_2 \left(\frac{S}{S_{max}} \right)^2 + a_3 \left(\frac{S}{S_{max}} \right)^3 + \dots \quad (17)$$

where a_1 , a_2 , and a_3 are -4 , $6\sqrt{3}/\pi$, and 1.404 , respectively. The RSA model has been modified later by considering colloid shape, Brownian diffusion, and colloidal forces (e.g., attractive colloid-surface DL interaction, repulsive colloid-colloid DL interaction, and gravitational force).

Ripening is opposite to blocking, referring to the process of deposited colloids on a collector surface favoring subsequent colloid deposition. Ripening occurs when the colloid-colloid interaction is more favorable compared to colloid-surface interactions. Ripening results in an increase of deposition rate with time and is denoted by a descending plateau in breakthrough curves from column experiments. To date, ripening can only be quantified using empirical models such as the second-order kinetics model. The mass balance equation for colloid deposition via ripening as a second-order process is expressed as

$$\frac{\rho_b}{f} \frac{\partial S}{\partial t} = k_r SC \quad (18)$$

where ρ_b is bulk density and k_r is colloid interaction rate coefficient.

Transport models

Transport of colloids in porous media has been simulated by abstract, mechanistic, and continuum scale models (Babakhani et al., 2017). Material flow analysis and multi-media models are abstract models developed based on the mass balance principle covering scales from global down to local levels. Most abstract models use simple algebraic equations, and only a few attempts have been made to address the influence of various factors on colloid transport.

Different from solutes that exhibit random motion, colloids have limited diffusive motion and possess largely deterministic trajectories. Therefore, the likelihood of colloids reaching collector surfaces can be mechanistically predicted. Lagrangian and Eulerian methods are the two most common mechanistic approaches for calculating the single collector removal efficiency η at the pore scale. Lagrangian methods describe trajectories of colloids governed using Newton's second law by considering the forces and torques acting on the colloids. Eulerian methods track colloid concentration distribution in time and space. For colloid transport and deposition in fluids, the distribution of colloid concentration is described by the convective-diffusion equation. The calculated single collector removal efficiency at pore scale is related to the deposition rate at continuum scale via upscaling, shown in detail below.

In continuum-scale models, microscopic properties are averaged over a representative elementary volume (REV) and the average property such as porosity and colloid concentration is treated as a value that represents the property throughout the REV (Molnar et al., 2015). Based on this assumption, the mass balance equations are solved at the macroscopic scale and partial differential equations that describe spatial and temporal rate of change of the key macroscopic properties are obtained. For example, the advection-dispersion equation with incorporation of terms (e.g., partition, deposition, and straining) has been frequently used to simulate the transport. Particularly, dual-deposition rate models and dual-region or multiporosity models have been developed. The values of parameters in these terms can be obtained by using the models to simulate data from experiments such as batch and column examinations.

Upscaling

The pore scale parameter η_p quantifies the transport of colloids from bulk solution to the vicinity of a collector surface and subsequent immobilization on a collector surface. The pore scale parameter η_p determined via the mechanistic models can be related to deposition rate k_d at continuum scale via the following expression

$$k_d = \frac{3}{2} \frac{(1-f)}{d_c f} U \eta_p \quad (19)$$

where d_c is collector diameter. Eq. (19) assumes that the control volume is depicted by a collection of identical pore-scale collectors consisting of the same volume and possessing the same porosity as the control volume (Molnar et al., 2015). This assumption has been validated by experimental observations. However, upscaling using Eq. (19) faces challenges under unfavorable conditions because of the accumulation of colloids in the near surface domain (e.g., via secondary-minimum association). The accumulation in the near surface domain can cause extended tailing in colloid breakthrough curves during elution in column transport experiments through: (1) long residence times of colloids in the near-surface fluid domain and (2) transfer of colloids in the near surface domain from upstream to downstream collectors (Johnson and Hilpert, 2013). The upscaling is further complicated at field scale due to the high heterogeneity of subsurface environments and the interaction of various transport processes (e.g., aggregation, deposition, release, straining, and blocking).

Conclusion

Colloid transport, the movement of particles of sizes from 1 nm to 10 μm , in soils and groundwater aquifers, plays crucial roles in many agricultural, environmental and engineering processes. These processes include transport of chemical pollutants, pesticides, fertilizers, microbial pathogens, manufactured nanoparticles and micro- and nanoplastics, as well as beneficial management practices such as water purification and filtration, groundwater remediation using microbes and nanoparticles, and petroleum reservoir production. Research on colloid transport through porous media in the last ~ 35 years has significantly improved our overall understanding. New advances are particularly notable in the following areas: (1) identification of colloid interactions in secondary minima and straining as important mechanisms of colloid retention in addition to deposition in primary minima under unfavorable conditions; (2) revealing mechanisms that control short-range forces and incorporation of the short-range forces into the classical DLVO theory to account for discrepancies between predictions from traditional theories and experimental observations; (3) development of theoretical frameworks to account for physical and chemical heterogeneity of colloids and collector surfaces; (4) initiation and making significant progress on research of colloid retention and transport in unsaturated media by identifying the roles that the AWI and the contact line play; (5) employment of advanced instruments and pore-scale investigations to significantly improve mechanistic understanding on the interactions and processes involved in colloid transport; (6) expanding the scope of colloid transport research from soil colloid mobilization, colloid-facilitated contaminant transport to include transport of microbial pathogens, manufactured NPs and micro- and nanoplastics.

Despite the significant advances, challenges and knowledge gaps remain. Models that are used to quantify colloid transport at realistic scales are largely empirical due to our incomplete understanding of the mechanisms involved, our inability to experimentally validate many of the assumptions used in these models, as well as the extremely complex nature of the subsurface porous media. These will be topics under continued investigation. Moreover, new areas of interest related to colloid transport in porous media will undoubtedly emerge. For example, the stability of soil organic carbon and its transport has been found to be closely related to its ability to complex with soil minerals, suggesting a potentially very important role that soil colloids may play in global carbon cycling. Another relevant topic that has attracted intense research attention is the fate and transport of micro- and nanoplastics in soil due to their widespread pollution in terrestrial systems. Therefore, colloid transport in porous media and its many applications will remain an active research topic in the foreseeable future.

Abstract

Solute transport is generally assumed to be as described by the advection-dispersion equation (ADE). But a wide range of observations leads to the conclusion that dispersion increases with scale (distance or time). That is, fitting the ADE to early-time dispersion data and extrapolating to later time will almost always underestimate the data that are (eventually) collected at that late time. This inconvenient finding has motivated extensive research and model development. Nonetheless, predictions of future dispersion frequently get the scaling wrong.

Glossary

ADE Advection-dispersion equation, a model of dispersive transport in which the solute travels at the mean fluid velocity, and disperses symmetrically as if it were diffusing.

BTC Breakthrough curve.

CLT Convective lognormal transfer, a specific kind of streamtube model, in which the distribution of streamtube velocities is given a lognormal form.

CTRW Continuous time random walk, a model of dispersive transport in which solute jumps between streamlines, with jump probability and timing governed by ancillary functions.

Dispersivity Dispersion coefficient divided by velocity.

FADE Fractional advection-dispersion equation, a generalization of the ADE using fractional calculus.

MIM Mobile-immobile, a model of dispersive transport in which transport takes place in the mobile region, with solute diffusing between the mobile and immobile regions.

MRMT Multi-rate mass transfer, a generalization of the MIM with many immobile regions, each exchanging solute with the mobile region at different rates.

PT Percolation theory, a conceptual model of porous materials and the pathways through them.

Streamtube model A transport model in which solute molecules flow along streamlines or streamtubes, and do not jump from one to another.

Transfer function See streamtube model.

Key points

1. Solute transport is commonly assumed to be as described by the advection-dispersion equation (ADE).
2. Dispersion is often observed to increase with scale (distance or time).
3. Many explanations and models have been proposed for this scale-dependence of dispersion.
4. We generally do not know in advance what model will best describe how dispersion in a given situation will evolve with time and/or distance.

Introduction

'Scaling of transport properties' refers to the common and often troublesome observation that the model parameters describing transport at one scale are frequently incorrect at another scale. The word 'scale' denotes extent, usually in space or time. Thus, to say that 'transport *scales*' is to say that different results are obtained from measurements made at different spatial or temporal scales. The most common situation is that one measures dispersion (using whatever metric one chooses) at a small scale and predicts it at a larger scale, only to find that the actual dispersion as measured later at the larger scale is greater than predicted. Dispersion coefficients compiled from many separate experiments tend to increase with distance. How a model parameter (such as the dispersion coefficient) changes with scale need not be linear: the exponent governing the coefficient's change with time or distance need not equal unity. Is this scaling intrinsic to the transport process itself, a function of the media, or both?

The concept of scaling is historically grounded in widespread use of the advection-dispersion equation (ADE), which uses a diffusion analogy to describe dispersive transport. To say that 'transport scales' often simply means that it does not conform to a simple diffusion-like description. Scaling of dispersion was initially thought to be an exceptional case, sometimes called 'anomalous dispersion,' implying that dispersion which conforms to the ADE is the norm. But so-called anomalous transport is increasingly understood as typical, with dispersion that conforms to the ADE ('Gaussian dispersion' or 'Fickian transport') now being seen as the special case.

This article discusses the simple case of one-dimensional longitudinal transport of a nonreactive, neutral, conservative solute during steady isothermal saturated flow, ignoring any density and viscosity differences between the native fluid (for example, the original soil pore water) and the 'new' fluid (say, soil pore water with a tracer or pollutant added). This simple case is already sufficiently difficult, and yet the reader is cautioned that real-world situations also include reactive, degrading, sorbing, or charged solutes moving non-isothermally and transiently under multiple driving and dispersing forces.

Scale

Soil science and hydrology are concerned with processes taking place from the micrometer scale to the kilometer scale and beyond, and from the essentially instantaneous to a geologic timescale. It is common to speak of scales in a colloquial manner—'pore-scale,' 'lab-scale,' 'overnight'—and the mental images that these terms invoke can be useful, although they are not quantitative. Less useful are terms such as 'microscale,' which carry widely different meanings between (and even within!) disciplines. Because soil science is inherently interdisciplinary, such words often have different meanings even to different soil scientists. If quantitative terms are needed, then using the size itself—for example, 'decimeter-scale'—can reduce ambiguity.

Some properties are specific to a defined range of scales. To illustrate, suppose one wants to measure the porosity of a sand using computed tomography (CT). If the CT unit measures with a resolution of 0.01 mm, then most voxels (volume elements from the CT scan) will represent either the inside of a solid particle or the center of a pore. In neither case will it be useful to speak of the porosity of an individual voxel: porosity is a property of a volume and becomes meaningless as that volume shrinks to a point. If we coarsen the scale slightly, each individual voxel will sample just a few grains and pores, and so individual measurements will be highly variable. But when porosity is measured over a sufficiently large number of grains and pores (at least 30 in each direction is common guideline), the measured value is stable. This illustrates the concept of the representative elementary volume (REV): the smallest volume over which a given property can be measured with reasonable confidence. Notice that the REV must be larger than the characteristic scale of variability of the medium (if one exists).

We must also distinguish between scale and level. Scale is strictly about physical extent, while level involves the emergence of new properties. The two are easily confused, because changes in physical size often entail changes in level also. As a trivial example, a soil core 10 cm deep may come from a single horizon, but 'scaling up' to a 20-cm core may yield a sample with two distinct horizons in it—a difference in level as well as scale. Likewise, scaling up from a 10-cm core to a pedon may introduce fractures or wormholes into the system, and so, rather than studying a soil matrix, one now faces a macropore-matrix or dual-permeability system. The distinction between scale and level may be quite subtle. For example, buoyancy effects may not be evident during fast flow of a weak salt solution through a 1-cm-diameter soil column, but they may be evident during slower flow through a larger-diameter soil column. In the second case, the increase in size (scale) allows the emergence of a previously negligible mechanism (level), so the second system under study is not equivalent to the first. It can be useful to compare relevant dimensionless groups to help discern

whether changing the scale also allows new processes to come into play. Relevant dimensionless groups may include the Péclet number (ratio of advective to diffusive forces), the capillary number (ratio of viscous to capillary forces), the Bond number (ratio of buoyancy to capillary forces), the Reynolds number (ratio of inertial to viscous forces), and the Schmidt number (ratio of kinematic viscosity to molecular diffusivity).

A further difficulty is that many parameters of interest can each be best measured within a fairly narrow range of scales. For example, dispersion is generally estimated from solute concentration, based upon samples at the scale of a liter or less. Measuring solute concentration over a large area is generally accomplished by collecting many small samples, because collecting the entire outflow of a large area is impractical if not impossible. So studies of dispersion generally operate at many scales: the scale of the individual observations (where different observations may themselves have different scales), the scale of the current composite (for example, the inferred pollutant plume based upon some 100 individual core samples), the scale of the desired prediction, and the characteristic scale, if any, of the soil's heterogeneity. While we are mainly concerned here with the disparity between the middle two (scale of the current composite and the scale of the desired prediction), any difference in scale may contribute to scaling.

Gaussian solute transport

Hydrodynamic dispersion (for convenience here called simply 'dispersion') emerges from the interplay of two mechanisms: mechanical dispersion and molecular diffusion. In simplest terms, mechanical dispersion is caused by the medium, while diffusion is inherent to the fluid. Mechanical dispersion results from differences in travel time along different streamlines. Streamlines differ in velocity due to heterogeneity of the medium, such as variations in pore size and connectivity, and the presence of structure across multiple scales from pore-scale correlations to larger-scale layering and fractures. When flow is rapid, mechanical dispersion contributes most of the total dispersion, while at slow flow rates diffusion is also evident.

Diffusion as a macroscopic phenomenon results from the random motion of solvent and solute molecules. The diffusion equation describes net solute flux as being proportional to, and opposite in direction from, the concentration gradient. In one dimension and in bulk fluid (no solid phase):

$$\frac{\partial C}{\partial t} = -D_{\text{aq}} \frac{\partial^2 C}{\partial x^2} \quad (1)$$

where C is solute concentration (M L^{-3}), t is time (T), D_{aq} is the diffusion coefficient ($\text{L}^2 \text{T}^{-1}$) of the solute in water, and x is distance (L). In the presence of a solid phase, the molecular diffusion coefficient can be adjusted by the porosity ϕ of the medium and the tortuosity τ of the diffusive path length, giving an effective diffusion coefficient: $D_{\text{eff}} = D_{\text{aq}} \phi / \tau$.

Dispersion is often estimated using data from an experiment in which a tracer is introduced into steadily flowing water. That source may be an instantaneous spike or a step input; for this illustration we assume a step. At a point downstream from where tracer was introduced, a steady increase in the solute's flux concentration is seen as the native water is replaced by water with the tracer (If instead the tracer's resident concentration were measured at multiple points inside the sample at a single instant, the concentration would be seen to decrease with distance downstream from its peak at the point of introduction.). The output of a flux concentration dispersion experiment can be summarized graphically using a break-through curve (BTC) (Fig. 1). For a laboratory experiment, the x-axis is typically presented in units of pore volumes, the amount of water needed to replace the original water in the sample precisely once. The y-axis is expressed as the ratio of the input concentration to the peak concentration, C/C_0 . This normalization of the two axes allows curves from different experiments (e.g., using different flow rates or column lengths) to be compared.

Fig. 1 Sample flux concentration breakthrough curves for: (A) a step input with piston flow; (B) a step input with Gaussian dispersion; (C) a Dirac (pulse) input with Gaussian dispersion; and (D) non-Gaussian dispersion of a step input. See text for explanation.

Spreading of solute in a tube

Griffiths (1910) showed that a drop of dye, placed into water flowing through a glass tube, moves at the mean water velocity, with its dispersion along the tube being symmetrical. Taylor's (1953) subsequent analysis showed that radial diffusion (normal to the direction of flow) explained the movement of solute molecules between the fast-flowing tube center and the negligible velocities near the wall. While diffusion is only one component of dispersion, Taylor showed that dispersion of a solute in fluid flowing steadily through a tube can—under certain conditions—be precisely described by superimposing the mean fluid velocity on a diffusion-like dispersion term. The main condition is simply that flow be sufficiently slow that solute molecules have time to diffuse freely between fast (tube center) and slow (tube wall) regions, a condition that is also well approximated, at least at the pore scale, under natural conditions in many soils and aquifers.

Taylor's papers on longitudinal dispersion of solutes in a tube, combined with further analysis by Aris (1956), shows that the dispersion behaves like diffusion, in the sense that it yields a Gaussian concentration profile the width of which grows in proportion to the square root of time (Fig. 2). Aris's theoretical expression for the dispersion coefficient D ,

$$D = D_{\text{aq}} + \frac{a^2 v_0^2}{192 D_{\text{aq}}} \quad (2)$$

where a is the tube radius (L) and v_0 the velocity (L T^{-1}) in the tube's center, gives the dispersion coefficient as the sum of diffusive and mechanical dispersive forces. For this equation to hold, $a^2/4D_{\text{aq}} t$ must be small: there must be sufficient time for radial diffusion to move molecules a distance equal to the radius of the tube. In terms of the Péclet number, this condition may be expressed as $Pe \ll 4 l/a$, where l is the distance from the dye injection point at which the measurement is made. When the elapsed time is too short, radial diffusion is insignificant and dispersion can be approximated via the parabolic velocity profile. Because for any given velocity and tube radius the time condition does not hold for some short time or distance, short times and/or distances are called 'preasymptotic.'

The conditions for Taylor's analysis can be shown by plotting the ratio of total dispersion to diffusion as a function of the Péclet number (Fig. 3). The solid line represents the Aris equation (Eq. 3), which shows different behavior in each of three regions; the dashed lines show the behavior that would be seen if the time condition were violated. In the first region, diffusion is the main contributor to total dispersion. In the second region, the slope of the line is approximately 2. The Péclet number above which the time condition fails, $Pe > 4 l/a$, is shown as a gray region rather than a single line because it changes for different l . In this third, preasymptotic region, dispersion is linearly related to velocity.

Taylor's and Aris's analyses established much of how both engineers and soil scientists now think about dispersion. The analogy thereby established between dispersion and diffusion has been broadly applied to solute movement in porous media. The analogy is particularly attractive because the diffusion equation has been widely studied, and operating within this analogy gives access to preexisting mathematical solutions. Concepts such as a particular aquifer test having preasymptotic flow conditions also derive from this history.

Fig. 2 Schematic of solute flowing and dispersing with distance in a tube into which it was introduced at a single instant.

Fig. 3 Mechanical dispersion for flow through a tube, divided by diffusion, as a function of the Péclet number. Above some Péclet number whose exact value varies with length, dispersion transitions to being linear with time; below that value, dispersion scales with the square of time. See text for explanation.

The advection-dispersion equation (ADE)

Superimposing a mean velocity on the diffusion equation yields the ADE, also called the convection–dispersion equation (CDE). A one-dimensional form of the ADE for nonreactive solutes describes the change in concentration as resulting from the sum of dispersive and advective terms:

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial x^2} - v \frac{\partial C}{\partial x} \quad (3)$$

where v is the average linear water velocity (L T^{-1}). An additional pre-factor R (retardation) for the lefthand side accounts for solute moving slower or faster than the water, generally caused by sorption. Analytical solutions to this equation have been derived for a wide variety of initial and boundary conditions, and several computer programs are also available. In a simple case, a point injection of a solute will move at the mean water velocity, while spreading as if it were diffusing with a diffusion coefficient equal in magnitude to the dispersion coefficient D . Even in soils and aquifers where dispersion is well described by the ADE, non-Fickian (or non-Gaussian) behavior is often seen at early times or short distances, then increasingly Fickian behavior will be seen with increasing distance or time. Accordingly, non-Fickian behavior is sometimes called ‘preasymptotic,’ implying that all transport eventually becomes Fickian. However, non-Fickian output is sometimes observed to persist across many length scales.

Dispersion is often observed to increase approximately linearly with fluid velocity. The ADE can in this case be generalized with respect to velocity by defining a dispersivity $\alpha = D/v$ (with units of L), and replacing the dispersion coefficient D in the ADE with α . This dependence on velocity may seem counterintuitive. If dispersion is the sum of molecular diffusion and mechanical dispersion, then mechanical dispersion (which results from the medium) should be independent of velocity, whereas slower flow (having more time) should result in greater diffusion-based dispersion. But as Taylor showed, D increases linearly with v within a specific range of Péclet numbers, so dispersion increasing with velocity is reasonable.

The assumption that dispersion can be treated mathematically as if it were diffusion often leads to a poor match between model and data. This is frequently because one or more of the equation’s assumptions have been violated: probably either the medium is not uniform (let alone tubular!) or there is insufficient exchange between solute molecules traveling on different streamlines. Interestingly, the ADE is unable to account correctly for dispersion resulting from vertical flow through layered soils (conceptually equivalent to different tubes in series, as shown in Fig. 4B): it predicts identical results regardless of which soil comes first, while experimentally the order of the layers affects the final value of the dispersion coefficient.

Because diffusion and flow are not strictly additive with respect to dispersion except under specific conditions, the basic concept of the ADE is not sufficiently general for many situations found in the real world. Much recent research on solute dispersion reveals struggles with the poor predictions produced by the ADE, frequently focusing on developing alternative conceptual models. In addition, the classical advection-dispersion (ADE) equation predicts that the dispersivity should be independent of length scale, while both lab and field experimental measurements imply the opposite (Molz et al., 1983; Neuman, 1990; Xu and Eckstein, 1995).

Alternatives to the ADE

Solute transport is often poorly described by the ADE, particularly when a porous medium is strongly heterogeneous. In heterogeneous formations, due to spatial heterogeneity, solute migration is characterized by features that do not conform to Fickian transport (Neuman and Zhang, 1990; Berkowitz et al., 2006). But even in homogeneous media such as sand packs, there is

Fig. 4 (A) A single tube with constant cross section, analogous to the ADE; (B) a tube with varying cross section, analogous to flow through a layered soil; (C) a bundle of tubes of different but constant cross sections, analogous to the CLT; (D) a single tube with dead-end 'pores', analogous to the MIM; and (E) a bundle of tubes of different cross sections with solute exchange between tubes, analogous to the CTRW.

evidence (Scheidegger, 1959; Lévy and Berkowitz, 2003; Bromly and Hinz, 2004) that solute transport displays non-Fickian behavior.

Alternatives to the ADE fall into two distinct groups: those that are built explicitly on the foundation of the ADE (dispersivity, MIM and MRMT, FADE), and those of independent provenance (CTRW, PT). All of these models other than PT are mathematically related. For instance, Dentz and Berkowitz (2003) demonstrated that there exists an analytical relationship between CTRW and MRMT. Metzler and Klafter (2000) showed that the time- and space-fractional ADEs are limit forms of CTRW. Furthermore, the fractional mobile-immobile model (FMIM) can be derived from the MRMT with a special memory function (Schumer et al., 2003). Finally, Sun et al. (2020) clarified the mathematical connections between CTRW, multi-rate mass transfer (MRMT), and fractional advection dispersion equations (FADE).

Mobile-immobile (MIM)

The mobile-immobile (MIM) model was first introduced in the petroleum engineering literature to explain dispersion in the presence of dead-end pores. It was adopted by van Genuchten and Wierenga (1976) in the soil physics community to describe dispersion in structured soils. The concept is that the soil is composed of mobile regions (such as interaggregate pores) through which most or all of the flow actually occurs, which are interconnected with immobile regions (e.g., the interior of aggregates) that exchange mass with mobile regions by diffusion only (Fig. 4D). The model can be considered to describe chemical sorption that is instantaneous at some sites and slow at others. The MIM model divides the domain into high- and low-permeability zones with appropriate coupling terms to account for the exchange of water and/or contaminants.

$$f_m \theta \frac{\partial C_m}{\partial t} + (1 - f_m) \theta \frac{\partial C_{im}}{\partial t} = f_m \theta D_m \frac{\partial^2 C_m}{\partial x^2} - v_m f_m \theta \frac{\partial C_m}{\partial x} \quad (4a)$$

$$(1 - f_m) \theta \frac{\partial C_{im}}{\partial t} = \mu (C_m - C_{im}) \quad (4b)$$

where θ is the volumetric water content, f is a water fraction (either mobile or immobile), the subscripts m and im refer respectively to the mobile and immobile zones, and μ is a first-order mass transfer coefficient ($L^2 T^{-1}$).

The MIM model given in (Eqs. 4a and 4b) is based on several assumptions, chief of which are (i) advective transport is neglected in the low-permeability zone, and (ii) solute exchange between the mobile and immobile zones is described via a quasi-empirical first-order rate term proportional to the difference between the average concentrations of the mobile and immobile zones.

Because diffusive exchange between regions is generally slow relative to advection, a given layer of soil is generally out of equilibrium with the solute flowing through it for some time, so this model is said to describe nonequilibrium flow. When the immobile region has zero volume, or when the diffusive exchange is instantaneous, the MIM reduces to the ADE; this extreme can be thought of as describing a soil of low heterogeneity. As might be expected from its close ties with the ADE, the MIM predicts identical scaling behaviors (Table 1). On a practical level, the MIM often suffers from nonunique solutions; that is, a given BTC may be equally well fitted by more than one single set of parameters. This non-uniqueness implies that the equation has too many fitting

Table 1 Scaling with time (T) of solute mass mean and standard deviation according to four transport models.

Model	Mean	Standard deviation	Standard deviation/mean
ADE	t	$t^{1/2}$	$t^{-1/2}$
MIM	t	$t^{1/2}$	$t^{-1/2}$
CLT	t	t	Constant
CTRW ($0 < \beta < 1$)	t^β	t^β	Constant
CTRW ($1 < \beta < 2$)	t	$t^{(3-\beta)/2}$	$t^{(1-\beta)/2}$

ADE, advection–dispersion equation; MIM, mobile–immobile model; CLT, convective lognormal transfer function model; CTRW, continuous-time random walk model.

parameters (three for the MIM versus one for the basic ADE), and casts some doubt on the physical interpretation of those parameters.

The MIM can be generalized by positing multiple components of the porous medium, each interacting with the fluid flow through its own rates and mass transfer coefficients; this is the Multiple-Rate Mass Transfer (MRMT) model of Haggerty and Gorelick (1995).

The MIM model is single-rate and predicts an exponential trend toward an asymptotic state where the mobile mass is a constant positive fraction of the injected mass. However, tracer measurements observed at the MADE site exhibited a continuous power-law decrease in mass recovery (Harvey and Gorelick, 2000). Such a power-law trend may be explained by a fractal distribution of rate coefficients. Schumer et al. (2003) generalized the traditional MIM model and proposed fractional MIM (FMIM) equations with power-law waiting times in the immobile zone. The FMIM model is equivalent to previous models of MIM transport with power law memory functions, and is the limiting case governing continuous time random walks with heavy tailed random waiting times.

Transfer functions

Another common conceptual model is the so-called streamtube model or transfer function model, in which solute transport is considered to take place through multiple parallel but noninteracting streamlines (Fig. 4C). Dispersion results from the differences in velocity among the various streamtubes. Because in principle it is possible to reproduce any possible breakthrough curve by generating the correct streamtube distribution, this method is very flexible. This model is essentially a multiple-tube equivalent of the dispersion that would result from flow in a tube in the absence of diffusion, and so, because their dispersion results from insufficient mixing, streamtube models may be considered to be preasymptotic. Streamtube models are most applicable to media in which flow really does take place through parallel but noninteracting pathways, such as horizontal flow through an aquifer with homogeneous layers of contrasting properties. Some variants of this model allow dispersion within each streamtube, while others assume no local dispersion (i.e., piston flow). One common version, Jury's convective lognormal transfer function model (CLT), specifies the distribution of the solute travel times (or, by analogy, the tube radii) and thus the form of the final BTC.

The streamtube models assume zero interaction between streamlines, in contrast to the ADE, which assumes that streamlines do interact. These two models therefore represent extremes along a continuum of streamline interaction. In principle, the streamtube model should better represent early or preasymptotic times, before streamlines have had time to intermix adequately, and the ADE later times.

While the ADE predicts that solute-spreading scales with the square root of time, the CLT predicts solute-spreading that scales linearly with time (Table 1). Solute movement that is consistent with a streamtube-like mechanism will therefore appear to scale if analyzed using the ADE; likewise, solute transport that is well described by the ADE will scale incorrectly if analyzed using the CLT.

Fractional ADE (FADE)

The classical ADE can be generalized through the use of fractional calculus. Meerschaert et al. (1999) were among the first to propose this by applying Lévy's family of stable distribution. They developed the fractional advection-dispersion equation:

$$\frac{\partial C}{\partial t} = -v \frac{\partial C}{\partial x} + D \frac{1 + \omega}{2} \frac{\partial^2 C}{\partial x^2} + D \frac{1 - \omega}{2} \frac{\partial^2 C}{\partial (-x)^2} \quad (5)$$

where $1 < \zeta \leq 2$ is the stable distribution index and $-1 \leq \omega \leq 1$ is the skewness. Eq. (5) with $\zeta = 2$ and $\omega = 0$ reduces to the traditional ADE model.

Initial models were space-fractional (fractional in space), meaning that the order of space in the partial differential equation is fractional, not necessarily an integer. Variants proposed later include the time-fractional dispersion equation with drift (Liu et al.,

Table 2 Summary of different models developed by means of fractional calculus (Kelly et al., 2017).

Model	Governing equation	Remarks
Space-fractional ADE (sFADE)	$\frac{\partial C}{\partial t} = -V \frac{\partial C}{\partial x} + D \frac{1+\omega}{2} \frac{\partial^2 C}{\partial x^2} + D \frac{1-\omega}{2} \frac{\partial^2 C}{\partial (-x)^2}$	ζ Stable index, ω skewness
Time-fractional ADE (tFADE)	$\frac{\partial^{\gamma} C}{\partial t^{\gamma}} = -V \frac{\partial C}{\partial x} + D \frac{\partial^2 C}{\partial x^2}$	γ Time-fractional exponent
Fractional mobile-immobile (FMIM)	$\frac{\partial C}{\partial t} = -V \frac{\partial C}{\partial x} + D \frac{\partial^2 C}{\partial x^2} - \kappa \frac{\partial^{\gamma} C}{\partial t^{\gamma}}$	γ Time-fractional exponent, κ capacity coefficient
Temporally tempered Lévy motion (TTLM)	$\frac{\partial C}{\partial t} = -V \frac{\partial C}{\partial x} + D \frac{\partial^2 C}{\partial x^2} - \kappa \frac{\partial^{\gamma+\lambda} C}{\partial t^{\gamma+\lambda}}$	γ Time-fractional exponent, κ capacity coefficient, λ tempering rate

2003), the fractional mobile-immobile equation (Schumer et al., 2003), and the temporally tempered Lévy motion model (Meerschaert et al., 2008) (Table 2).

Kelly et al. (2017) stated that “While sFADE [space-fractional ADE] provides acceptable fits for the BTCs under consideration, sFADE does admit nonphysical behavior (negative dispersion) that may manifest itself at other measurement locations or times.”

Continuous-time random walk (CTRW)

Continuous-time random walk (CTRW) theory has also been used to study contaminant migration. It is based on the generalization of the “random walk” method where the particle transition times, as well as jump lengths, are accounted for. The CTRW has been successfully developed by Berkowitz, Scher, and co-workers to quantify non-Fickian transport in a broad variety of porous and fractured media. The basis of the CTRW framework is the portrayal of transport as a sequence of transition rates and the incorporation of the full spectrum of these rates into the transport equations.

The CTRW is derived from the Master equation of statistical mechanics using appropriate memory functions to represent non-Fickian behavior. Within the CTRW framework, the transport equation in one dimension and Laplace space is

$$u\tilde{C}(x, u) - C_0(x) = -\tilde{M}(u) \left[v_t \frac{\partial}{\partial x} \tilde{C}(x, u) - D \frac{\partial^2}{\partial x^2} \tilde{C}(x, u) \right] \quad (6)$$

where $\tilde{C}(x, u)$ is the Laplace transform of concentration at location x , u is the Laplace variable and $\sim$ indicates Laplace space, $C_0(x)$ is the initial concentration at location x , and v_t is the transport (solute) velocity.

In Eq. (6), $\tilde{M}(u)$ is the memory function that accounts for the unknown heterogeneities at the pore scale and is given by (Berkowitz and Scher, 2009)

$$\tilde{M}(u) = t_1 u \frac{\tilde{\psi}(u)}{1 - \tilde{\psi}(u)} \quad (7)$$

where t_1 is a median time for transitions between pore bodies, and $\tilde{\psi}(u)$ is the transition rate probability and the Laplace transform of $\psi(t)$, the waiting (or transition) time distribution. In the literature, various choices of $\tilde{\psi}(u)$, such as decoupled and coupled joint distributions have been made to determine $\tilde{M}(u)$ in Eq. (7). For example, in the earlier framework of the CTRW, a simple power law such as $\psi(t) \sim t^{-1-\beta}$ was applied (Scher et al., 1991). Geometry and velocity distributions, in conjunction with particle mixing rules, were also used to map the particle movement between fracture intersections onto a joint probability density $\psi(s, t)$, the probability per time for a transition between fracture intersections separated by s with a difference of arrival times of t (Berkowitz and Scher, 1998).

At sufficiently large time, the transport in a real system will become Fickian at length scales sufficiently greater than the largest heterogeneity scale meaning that the medium acts as a more homogeneous system. This behavior can be suitably addressed using the following truncated power-law (also known as TPL) version of $\psi(t)$, which enables detailed investigation of the transition from non-Fickian to Fickian transport:

$$\psi(t) = \left[\left(\frac{t_1}{t_2} \right)^{\beta} \exp \left(\frac{t_1}{t_2} \right) \Gamma \left(-\beta, \frac{t_1}{t_2} \right) \right]^{-1} \frac{\exp(-t/t_2)}{t_1 (1 + t/t_1)^{1+\beta}} \propto \exp(-t/t_2) (1 + t/t_1)^{-1-\beta} \quad (8)$$

where t_1 and t_2 are the limits of the power-law spectrum, $\Gamma(a, x)$ is the incomplete Gamma function, and β is the exponent of the waiting (or transition) time distribution. β typically ranges between 0 and 2. The value of β is non-universal, meaning that it depends on the heterogeneity and morphology of the porous medium.

In Eq. (8), $\psi(t) \sim (t/t_1)^{-1-\beta}$ for $t_1 \leq t \leq t_2$, and $\psi(t)$ decreases exponentially for $t \geq t_2$. The interplay between β and t_2 has a substantial impact on the entire shape of a migrating solute plume (Berkowitz and Scher, 2009). By fitting the CTRW solution to either experimental data or numerical simulations, different values of β e.g., between 0 and 1 (Cortis and Berkowitz, 2004), 1 and 2 (Berkowitz and Scher, 2009), and > 2 have been reported in the literature. Fickian-like transport (Gaussian behavior) arises when $\beta > 2$, in agreement with the central limit theorem. The $0 < \beta < 2$ range corresponds to highly heterogeneous porous media. An attractive aspect of the CTRW is that fitting a breakthrough curve gives an estimate of β , which also indicates how the transport will scale.

Percolation theory

Percolation theory can be applied to study porosity- and saturation-dependent treatment of dispersion in porous media using the concepts from critical path analysis, cluster statistics of percolation, and fractal scaling of percolation clusters (Hunt and Skinner, 2008; Ghanbarian-Alavijeh et al., 2012). Within the percolation theory framework, one can calculate spatial solute distributions at an instant in time and arrival time distributions as a function of system size and properties of the medium. Unlike all the previous models, percolation theory is not derived from or related to the ADE.

One first models the pore space of the medium by assuming that the pore size distribution follows a specific type of probability density function, for example a power law. The pore size distribution leads to the probability distribution of the hydraulic conductance, g , for a given water content θ and distance from the source x as follows (Hunt et al., 2014)

$$W(g|x; \theta) \propto Ei \left[\left| 1 - \left(\frac{g}{g_c} \right)^{\frac{3-D_p}{3}} \right| \left[\left(\frac{x}{L} \right)^{\frac{\xi - \phi + \theta - \theta_c}{\xi - \theta_c}} \right]^{\frac{2}{v}} \right] \quad (9)$$

where Ei is the exponential integral, g is the hydraulic conductance, g_c is the critical hydraulic conductance, D_p is the pore space fractal dimension, v is the universal exponent of the correlation length (equal to 0.88 in three dimensions), ξ is the parameter of the generalized power-law distribution (Ghanbarian-Alavijeh et al., 2012), and θ_c is the critical water content for percolation.

The probability distribution function for solute arrival times in a system of length x , $W(t|x; \theta)$ is found using the identity $W(t|x; \theta)dt = gW(g|x; \theta)dg$. To apply such an identity, one must first have an expression for the typical transit time, $t(g|x; \theta)$ of a cluster of length x and controlling conductance g . The typical time for transport through such a cluster is generated by isolating the effects of cluster topology and the conductance distribution. If one solves for the saturation dependence of $t(g|x; \theta)$ for the power-law pore-size distribution model, the result is (Ghanbarian-Alavijeh et al., 2012)

$$t(g|x; \theta) = \left(\frac{x}{L} \right)^{D_b} \frac{t_0 D_p}{3 - D_p} \frac{\left[\left(\frac{g_c}{g} \right)^{1 - \frac{D_p}{3}} \left(\frac{\xi - \phi + \theta}{\xi - \phi + \theta - \theta_c} \right) - 1 \right]}{\left[1 - \left(\frac{g}{g_c} \right)^{\frac{D_p}{3}} \left(\frac{\xi - \phi + \theta - \theta_c}{\xi - \phi + \theta} \right)^{\frac{D_p}{3-D_p}} \right]} \left[\frac{1}{(\xi - \phi + \theta - \theta_c)^{(D_b-1)v}} \right] \left[\frac{1}{1 - \left(\frac{g}{g_c} \right)^{1 - \frac{D_p}{3}}} \right]^{(D_b-1)v} \quad (10)$$

where D_b is the backbone fractal dimension described below.

All the parameters in Eq. (10) have a physical meaning. Recall that the exponent for the correlation length, v , is universal and equal to 0.88 in three dimensions (Hunt et al., 2014). The exponent for the fractal dimensionality of the backbone is known to have only a limited variability (in particular with flow dimensionality and whether the percolation problem is random or invasion). However, it could also have a wide range of values if the pore space is correlated depending on the level of correlation. The critical volume fraction for percolation θ_c will not typically be known, but a good estimation can be made from soil water retention data, where it can be identified with the minimum water content measured (residual water content). The fractal dimensionality, D_p , and the parameter ξ can also be extracted from the soil water retention curve.

Ghanbarian-Alavijeh et al. (2012) applied the percolation theoretic approach, Eqs. (9) and (10), to determine the scale dependence of dispersivity, compared with more than 2200 experiments measured over 10 orders of magnitude of length scale, and found good agreement between the theory and experiments. Specific comparisons of predictions for arrival time distribution with experiments on a single column over a range of saturations also demonstrated that their model is accurate and predictive.

Sahimi (2012) applied power-law scaling laws from percolation theory and linked the exponent β in the CTRW model to scaling exponents characterizing power-law behavior of electrical and hydraulic conductivities, as well as correlation length, percolation probability, and accessible fraction of pores on the sample spanning cluster. Sahimi (2012) argued that nonuniversality of β could be due to the nonuniversality in continuum systems or in percolation models with long-range correlations.

Observations and mechanisms

There is a strong tendency for dispersivity to be greater at larger scales, as documented in several meta-analyses (e.g., Neuman, 1990; Schulze-Makuch, 2005). Unfortunately, the scatter in the data is great enough that no universal scaling behavior can unambiguously be inferred. While the cause of this trend is not clear, the most common explanation is that, as a solute travels farther, it encounters increasing scales of heterogeneity. This means that, at larger scales, solute molecules will on average sample a larger range of velocities than they did at a smaller scale. The travel time for each molecule is the sum of many different times at many different velocities; increasing the range of velocities will therefore (assuming random and independent sampling by each molecule) result in a wider distribution of travel times and thereby a larger dispersivity. A fractal medium, with its ever-increasing scale of heterogeneity, results mathematically in dispersivity increasing with distance, i.e., scaling.

But increasing scales of heterogeneity are apparently not necessary for scaling to occur. For example, one laboratory experiment used a two-dimensional flow cell packed with two sands: 16% of the volume consisted of blocks of fine sand randomly placed within a coarse sand matrix, with the hydraulic conductivities differing by a factor of 20. Within approximately 1 m, the fitted dispersivity increased from 0.073 to 0.127 m. The skew of the data was fairly constant, suggesting that a change from preasymptotic

to asymptotic behavior was not occurring. Similarly, the Borden aquifer tests saw dispersivity increase by a factor of 8 over a distance of some 10 m in what was considered a homogeneous sand. And of course dispersion that occurs primarily through a streamtube-like mechanism, wherein regions that differ in velocity are isolated from each other, will also show scaling of ADE-calculated dispersivity.

Discussion of the 'scale of heterogeneity' also raises the question of the importance of heterogeneity at smaller scales. If much of dispersion is driven by heterogeneity, and that heterogeneity exists at all scales, then presumably the nature of the heterogeneity below the scale of heterogeneity is also important. But because both models and measurements are blind to processes below their respective finite-size scales, there are always smaller-scale processes that they cannot take into account, but which still influence the large-scale outcome. An exclusive focus on the largest-scale heterogeneities implicitly assumes that the smaller-scale heterogeneities are either negligible or diffusive in nature, but neither is necessarily the case. The smaller-scale influences can be significant and non-diffusive; for example, the presence of undetected cracks or wormholes in a soil profile may lead to arrival of solute at the water table well in advance of prediction.

Soils and other geologic porous media are neither purely random nor purely structured; instead they vary in their degree of randomness across most or all scales. But while understanding of soil properties has historically concentrated on the measurements themselves, and only relatively recently on the spatial structure of the properties, generally the topological structure is still ignored. As a consequence, researchers in the theory of contaminant transport have long considered (for example) what proportion of an aquifer is sand or clay, and even how thick the average sand layer might be, but not the question of whether there is a continuous sand pathway through the system. Continuity and interconnectedness are critical to diffusive and advective exchange across streamlines, and to the range of velocities encountered within a given streamline. They therefore make the difference between the ADE and streamtube models, and so are critical determinants of the scaling behavior of a given soil or aquifer.

In most situations, solute transport in soils or other geologic porous media is subject to all of the mechanisms mentioned so far: diffusive exchange between neighboring streamlines, parallel pathways with little exchange between them, and diffusive exchange between more and less mobile regions of the medium. There are also other important dispersive processes, such as advective (and even turbulent) exchange between streamlines, streamline-specific sorption based upon mineralogy, biodegradation based upon differences in microhabitat, and streamlines with nonconstant velocity, that do not show up in these models. Certainly the extent to which each mechanism contributes to dispersion is difficult to determine in advance, nor can one know in advance whether the length scale at which dispersion is to be predicted is greater than or less than the scale of heterogeneity (if any) of the medium.

In summary, predicting the scaling of transport is quite uncertain. New mathematical models such as FADE and CTRW give great flexibility in fitting, and open the possibility of gaining hints about the scaling. This is a topic that continues to advance. Nonetheless, natural systems are complex, and the practitioner should not assume that answers will be easy, nor early answers correct.

Abstract

Soils play an important role in controlling both the hydrologic and biochemical interaction between the land surface and the underlying groundwater system. A dynamic synergy exists between how soil processes influence groundwater quantity and quality and how the nature of groundwater flow influences soil water content and composition, and surface water ecology. The soil zone functions as both a reactive filter for infiltrating water and a region of infiltration above the water table facilitating the replenishment of groundwater resources. Rapid anthropogenic development combined with the uncertainties of a warming climate are leading to observable depletion of the groundwater resource, along with poorly understood, yet potentially significant changes in the complex interaction between soils and groundwater.

Key points

- Importance of groundwater in the global water balance
- Fundamentals of groundwater flow systems
- Influence of soils on groundwater quality and quantity
- Biogeochemical characteristics and interactions between soils and underlying groundwater resources
- Conjunctive interaction between soils and groundwater and impacts on aquatic ecology and groundwater contamination

Introduction

Within the global inventory of freshwater, groundwater accounts for approximately 30% of the overall total, yet it is estimated to represent close to 95% of the accessible, unfrozen freshwater resource (UNESCO, 2022). Groundwater is relied upon as a municipal, industrial and agricultural water source worldwide, providing more than half of the irrigation water demand, and representing the primary water source for over two billion people. Groundwater also plays a significant role in sustaining aquatic ecosystems, ranging from wetlands to streams and lakes, and functions as a strategic reserve in times of drought. As surface water resources are approaching or exceeding their allocation limits worldwide, groundwater is being relied upon progressively to support a wide variety of human needs. Warming climatic trends have begun to influence the replenishment, storage and temperature of groundwater, although the long-term impacts on the resource remain uncertain (Earman and Dettinger, 2011).

Both the quantity and quality of groundwater resources are facing unprecedented challenges from anthropogenic activities and changing climatic drivers. Overexploitation has resulted in more than half of the world's main aquifer systems being depleted at a rate greater than the natural replenishment. This has resulted in the loss of critical baseflow required to sustain terrestrial water bodies and has led to excessive land subsidence in some areas. Overpumping has resulted in the progressive capture of deep, lower

quality groundwater, causing the chronic degradation of regional groundwater quality by geogenic contaminants (Levy et al., 2021). The legacy of agricultural land management and municipal and industrial growth worldwide has resulted in the extensive contamination of vital groundwater supply systems, leading to adverse human health and ecosystem impacts. Despite the strategic value of groundwater, it remains poorly understood, quantified and managed at a global scale.

Groundwater is conventionally defined as the water that fills the pores, fractures and open cavities within subsurface materials beneath the phreatic level or water table, which is generally referred to as the saturated zone. Below the water table fluid pressure is considered positive, exceeding atmospheric pressure. The region overlying the water table and extending to ground surface is referred to as the vadose zone, where the residing pore water is held in tension within the pore network and subsurface materials are predominantly variably saturated (Fig. 1). Pore water tension (matric potential) may be highly variable both spatially and temporally within the vadose zone with greater tensions leading to smaller degrees of saturation as illustrated in Fig. 1. Near the water table, pore water tensions are generally low and the geologic materials in this region may remain saturated as water is held by capillarity of the pores. This is referred to as the zone of tension saturation or the capillary fringe (Fig. 1). The upper section of the vadose zone contains the soil water zone, which represents the interface between the ground surface and the variably saturated materials overlying the groundwater system (Fig. 1). The soil zone can be highly variable in thickness, mineral composition and in its physical, chemical and microbiological nature.

The majority of the rooting zone for terrestrial vegetation is contained within the unsaturated soil zone and it is normally characterized by its large component of organic carbon. Surface vegetation, the soil zone, and shallow groundwater are closely interlinked, often described and studied together as one unit referred to as the Critical Zone. The soil zone represents a vital component of the Critical Zone (Lin, 2010) (Fig. 1) controlling infiltration of terrestrial water and possessing a large capacity for geochemical and biological reactivity, which can significantly influence the soil water quality. As such, the Earth's surficial soils can fundamentally influence both the quality and quantity of groundwater at the local and regional scale. The nature of this influence depends on the physical, chemical and biological characteristics of the soil, which are in turn affected by local climatic conditions. The intrinsic interaction between soils and groundwater is the primary focus of this chapter.

Groundwater hydrology

Water contained within the terrestrial subsurface is conventionally compartmentalized as soil water and groundwater. Soil water exists within the variably-saturated vadose zone normally under fluid pressures lower than ambient atmospheric pressure (or tension). Groundwater is defined as the vast reserve of subsurface water that exists below the water table under fully saturated conditions at positive pressures at or above atmospheric pressure (Fig. 1). In soil physics, the term matric potential refers to the tension, with negative values (tension) in the vadose zone, whereas the positive pressure in the groundwater shows the pressure potential. The interaction between soil water and groundwater has wide ranging implications for the quantity and quality of water throughout all components of the global water balance.

Fig. 1 Conceptual diagram of the shallow subsurface showing the transition from ground surface through the soil and vadose zones to groundwater. The relationship between pore water content and pressure head is provided in the illustration on the right.

Groundwater occurrence

At a global scale, an estimated 68% of freshwater is trapped in glacial ice with, remarkably, only 1%–2% in surface water systems including all of Earth's lakes and rivers. The balance of the total freshwater exists as groundwater. The amount of freshwater circulating through the soil zone is an extremely small fraction of the overall global water balance (Shiklomanov, 1993). Groundwater provides drinking water to over 50% of the world's population and accounts for about 25% of all anthropogenic freshwater needs on Earth (UNESCO, 2022). Relative to surface water, groundwater exists as a highly accessible resource in most areas of the world, making it available to a wide range of users, including communities and industries. As such, it has tremendous societal and economic value, yet it remains poorly understood and undervalued.

The occurrence and movement of soil water and groundwater varies both spatially and temporally due to the complexity of the physical conditions within the subsurface and the changing hydrologic conditions throughout the annual cycle. Groundwater exists within lithified or consolidated geologic strata (rock) and non-lithified or unconsolidated strata (loose sediments) below the water table. The characteristics of the sediments influence the mobility, quality and accessibility of the groundwater resource. Of critical importance in understanding the occurrence and movement of groundwater are the physical parameters that define the permeability and porosity of the geologic material within which groundwater occurs. These parameters influence both the ease with which groundwater can flow under a driving force (permeability) and the storage capacity (porosity). Key controlling parameters include:

- **Porosity:** volume of voids per unit volume of the porous medium.
- **Effective porosity:** volume of interconnected voids per unit elementary volume of the porous medium. While porosity is a local measure of the total water storage capacity, effective porosity is a local measure of the well-connected pore space through which water actually moves.
- **Specific storage:** volume of water released from (or taken into) storage per unit volume of porous medium, per unit decline (or rise) of the piezometric (hydraulic) head.
- **Storativity:** equates to the specific storage multiplied by the saturated thickness of the geologic unit at the given point.
- **Specific yield:** the volume of water that is released from storage in an unconfined aquifer (explained below) per unit drop in the water table. The specific yield of an unconfined aquifer is larger than the specific storage of a comparable confined aquifer due to the process of actual dewatering and draining of the soil pores which occurs in the unconfined setting.
- **Permeability (or intrinsic permeability) and hydraulic conductivity:** permeability is a characteristic of the void space which affects its ability to transmit a fluid and is related to the size and interconnectivity of the pores within the sediment or rock. Hydraulic conductivity is directly related to the permeability of the porous medium but also incorporates properties of the fluid, such that it is directly proportional to fluid density and inversely proportional to fluid viscosity.
- **Transmissivity:** the discharge of groundwater through a unit width of the saturated zone as a result of a unit hydraulic gradient. Transmissivity, at a given point in the horizontal plane, equals the hydraulic conductivity, multiplied by the saturated thickness of the aquifer at the given point.
- **Hydraulic head and hydraulic gradient:** hydraulic head in the subsurface refers to a measure of the fluid potential of the water at the point of measurement and is a combination of the fluid pressure and the gravitational potential energy related to the elevation of the water above a chosen datum point, which is commonly taken as sea level. The hydraulic gradient is the rate of change in the hydraulic head over a specified distance in the direction of flow and is often referred to as the driving force of subsurface water flow.

Natural geologic strata containing groundwater are often categorized as either aquifers or aquitards. Aquifers consist of relatively permeable materials and are capable of providing useful or economically-feasible volumes of water when pumped for anthropogenic uses or which supply significant replenishment through upward seepage to surface water bodies such as lakes, streams and wetlands. Examples of typical consolidated aquifer materials include sandstones, porous or karstic limestones and highly fracture rocks, and some examples of unconsolidated aquifer materials include glacially-deposited sands and gravels, fluvial and alluvial sediments and coarse eolian deposits (Fetter and Kremer, 2021) (Fig. 2). Geologic units with low permeability, where groundwater flow is reduced, are referred to as aquitards and are often characterized by finer grained materials. Rock types like shale, granite and unfractured carbonate rocks are examples of consolidated aquitards and clay, glacial till and fine silts are examples of unconsolidated aquitards. Groundwater strata are further defined as being *unconfined* if bounded from above by the phreatic surface or the water table or *confined* when an aquifer unit is bounded from above by an aquitard of lower permeability such that the hydraulic head within the aquifer unit exists at levels higher than the elevation of the interface between the aquifer and the aquitard (Fig. 2). Aquifer and aquitard units are frequently encountered in layered sequences and when the aquitard units are permeable enough to permit a reasonable transmission of water vertically between the aquifer units, the aquifers are referred to as being *semiconfined*. The regional movement of groundwater through the complex subsurface environment is influenced by the distribution and nature of the annual replenishment of meteoric water recharging the groundwater flow system through the surficial soil zone as described below.

Groundwater flow

Groundwater is normally in a state of permanent motion from areas of natural and artificial recharge to points of natural and artificial discharge. Renewable groundwater is part of the hydrologic cycle, as seasonal meteoric and surface waters percolate

Fig. 2 Regional groundwater flow system from recharge to discharge areas through natural geologic units, including confined and unconfined aquifers and low permeability aquitards.

downward through the soil and unsaturated zone to the saturated portion of the subsurface, driving groundwater flow from areas of recharge to natural discharge outlets such as springs, wetlands, streams, lakes, and oceans (Fig. 2). The vadose zone, including the soil horizons, functions as a highly dynamic and reactive filtering agent overlying the groundwater flow system (Figs. 1 and 2). The permeability, composition and thickness of the vadose zone controls seepage rates and the chemical or biological reactivity above the water table, influencing the infiltration timing, distribution and water quality in recharge areas (Fig. 2). The characteristics of the shallow soil zone are highly variable spatially and transient, fundamentally influencing groundwater both locally and regionally. This is addressed in a subsequent section. The movement of groundwater within the saturated zone is usually slow and variable, ranging from millimeters per year up to meters or tens of meters per day. As a result, the residence time or age of water in the saturated zone (i.e., the time it takes to travel from its point of entry into the saturated zone to the point of discharge) may range from several weeks to thousands of years. The length of time groundwater remains within the subsurface influences its chemical nature due to the water-rock or sediment interaction that occurs along the flow path, which will also be discussed in more detail in a subsequent section.

The rate or flux of groundwater in the subsurface is described by a variable, termed specific discharge. It is defined at any point as the volume of water which passes per unit time through a unit area of porous medium perpendicular to the direction of flow at that point. Because flow takes place through the void spaces only, the average groundwater velocity is estimated by dividing the specific discharge by a factor equal to the effective porosity, defined earlier. The quantification of groundwater flow conventionally relies on Darcy's Law, which defines the specific discharge as the product of the hydraulic gradient and the hydraulic conductivity. Groundwater moves from regions of high hydraulic head to regions of low hydraulic head. By measuring hydraulic head distribution within the subsurface with a network of piezometers or monitoring wells and combining these data with laboratory (e.g., grain size analysis, permeameter) or in situ (e.g., single well response tests, pumping tests) estimates of hydraulic conductivity, groundwater flow direction and rate can be determined at local or regional scales (Fetter and Kremer, 2021). Due to the inherent geologic heterogeneity within the subsurface (hydraulic conductivity and porosity) and the transient nature of the hydraulic factors driving the flow system (recharge, discharge and hydraulic gradient), groundwater flow is highly variable both spatially and temporally.

Geochemistry of groundwater

The dissolved chemical load within natural groundwater is influenced by the chemical composition of infiltrating surficial waters, interactions within the vadose zone, specifically within the soil horizons and the nature of the geologic materials that groundwater encounters along its flow path from recharge regions to discharge points. Infiltrating precipitation will enter the shallow soil environment with an initial aqueous geochemical composition that reflects the local atmospheric conditions. In most cases the

water will have a relatively neutral pH, low total dissolved solids (TDS) and high dissolved oxygen (DO) concentration. Once within the shallow vadose zone, the infiltrating water enters a chemically and biologically reactive environment associated with the soil horizons where the chemical composition may change due to a wide range of reactions. In addition, chemical constituent concentrations may increase as a result of the removal of soil water through evapotranspiration (Poeter et al., 2020). As a result of the combined effect of open access to atmospheric oxygen and the production of carbon dioxide (CO_2) through root respiration and organic decay, the shallow vadose zone can be highly reactive where the development of acidic conditions within the infiltrating porewater results in the dissolution of soil minerals and subsequent increases in TDS. In addition to an increase in ionic composition of the infiltrating porewater, other soluble species including forms of carbon, nitrogen and chemicals derived from surface sources of contamination may also migrate through the shallow vadose zone. The fate and transport of these different species will be influenced by biogeochemical reactions within the soil horizons and the underlying unsaturated zone as discussed in more detail below.

Once the infiltrating water passes through the vadose zone and enters the groundwater flow system, the geochemical composition will continue to evolve. This evolution depends primarily on the chemistry of the recharge water from the vadose zone, the physical and mineralogical makeup of the geologic materials the groundwater will flow through, and the residence time within the subsurface. As the groundwater encounters a diverse assemblage of minerals along the flow path, dissolution will cause concentrations of major, minor and trace constituents to increase depending on the solubility of the constituent, dissolution rates and the length of time the water is exposed to specific mineral types. This is often referred to as water-rock interaction. In the case of a short residence time (e.g., <1 year), the geochemical composition of the groundwater may be very similar to that of the recharge water. However, older groundwater that has remained in the subsurface for much longer time periods (perhaps millennia), are frequently characterized by much greater TDS values, in some cases close to that of seawater (Poeter et al., 2020). Although the chemical composition of groundwater can vary widely, the ionic species that account for the majority of the mass of dissolved solids (>95%) include the cations calcium (Ca^{2+}), sodium (Na^+), and magnesium (Mg^{2+}) and the anions bicarbonate (HCO_3^-), chloride (Cl^-) and sulfate (SO_4^{2-}). Typical minor constituents include iron (Fe^{2+}), potassium (K^+), nitrate (NO_3^-), manganese (Mn^{2+}), silicon (Si^{4+}), fluoride (F^-) and dissolved organic carbon (DOC), but these tend to occur at much lower concentrations (Poeter et al., 2020).

Groundwater contamination

Both natural processes and anthropogenic activities can result in the contamination of groundwater at local and regional scales. As outlined in the previous section, groundwater with extended subsurface residence times can contain high levels of major and minor dissolved constituents that may exceed human or animal recommended drinking water limits. This can include high levels of salts in salinized groundwater that can result in soil salinity over very large areal extents (Scanlon et al., 2007; Poeter et al., 2020; Hassani et al., 2020). These are examples of natural processes leading to groundwater contamination resulting in degradation of water quality and potential impacts on soil characteristics. Anthropogenic sources of groundwater contamination are conventionally grouped in two categories: point and nonpoint or distributed sources (Fig. 3). Examples of point sources are landfills, septic weeping beds, above and below ground storage tanks for hazardous liquids, fuel stations and accidental spills. Point sources of contamination tend to be local in nature although over long periods of time, can result in spatially extensive regions of contaminated groundwater. Examples of nonpoint (distributed) sources include land application of agrichemicals, irrigation with poor-quality waters, atmospheric deposition of pollutants and urban runoff including road de-icers (Fig. 3). These produce large-scale effects in both time and space, which are often overlapping and difficult to monitor and relate to each source separately.

Numerous cases of groundwater contamination, particularly from landfills, mine-tailings, agricultural fertilizers and industrial operations have been documented worldwide. It is worth noting that, except for particular cases of direct contact between local sources and outlets of water and/or contaminants, the effects from most of the above-mentioned sources of groundwater contamination are not immediate. Due to flow of contaminants through soil to groundwater, there can be a long time-lag between the release of a contaminant to the subsurface and the detection of its impact on a groundwater receptor such as a public supply well or surface water body. The fate and transport of a specific pollutant will depend on the thickness and reactive nature of the soil and vadose zone, the flow path and residence time within the saturated zone, and the natural degradation and transformation capacity of the subsurface materials along the flow path. Processes such as adsorption, ion exchange, dilution, and chemical and biochemical reactions can all influence the nature and persistence of a wide range of groundwater contaminants. Once groundwater becomes contaminated, however, it will usually require a very expensive and time-consuming effort to achieve a desired level of clean up or remediation, if it is even technically feasible to achieve. Groundwater remediation strategies and technologies are extremely active areas of research and engineering practice (Fetter et al., 2018).

A specific groundwater contaminant category of global concern relates to water borne pathogens such as some strains of *Escherichia coli* (*E. coli*) bacteria and viruses, which can represent a significant and immediate threat to human health. Bacteria are generally not mobile in sand aquifers because they are large enough to be filtered out by the sand, but can be mobile in gravel aquifers, porous or karstic limestone and fractured rock aquifers. Viruses, which are much smaller, are more mobile than bacteria in aquifers. Harmful viruses can remain active for as long as 3 years and may travel many kilometers in high permeability aquifers (Poeter et al., 2020; Taylor et al., 2004). Microbiological water quality testing typically relies on fecal indicator bacteria, such as *E. coli*, that are easy to detect in water samples and their presence is an indicator of the potential presence of human pathogens

Fig. 3 Examples of point and diffuse sources of contamination resulting in zones of soil and groundwater contamination in the vicinity of a public water supply well.

including viruses. Although there are now effective methods for sampling and analysis of viruses in well water, such testing is rarely done, so that the frequency of illness attributable to viruses in groundwater is poorly known.

Groundwater as a natural and anthropogenic resource

Groundwater, as a natural resource, plays a fundamental role in supporting aquatic ecosystems, surface water flows, reservoir levels and diverse anthropogenic demands. While groundwater accounts for over 95% of the planet's liquid fresh water, it also provides approximately 50% of the total drinking water supply worldwide and 43% of all water used for irrigation (UNESCO, 2015, 2022). As surface water allocations reach maximum sustainable limits, groundwater will be required to meet increasing water demands from all sectors. Under projected warming climatic scenarios, the availability of surface water resources may become less reliable in some regions (Erler et al., 2018). Because groundwater tends to be more protected from variable climatic conditions due to the immense storage capacity within the subsurface reservoirs and protection from losses through evapotranspiration, it represents a relatively resilient and secure water source, particularly under conditions of extended drought.

Although groundwater is considered a renewable resource, being replenished through the annual precipitation cycle, the sustainable extraction capacity is finite. Overexploitation of aquifer systems worldwide has resulted in a continual lowering of groundwater levels, land subsidence and depletion of aquifer storage volume (Scanlon et al., 2012). The implications of lowering groundwater levels are perhaps most acutely observed in relation to the effect on surface water systems and terrestrial aquatic ecosystems. Groundwater supplies a relatively continuous form of replenishment to surface water systems including streams and lakes in the form of baseflow (de Graaf et al., 2019). The release of relatively warm groundwater during frozen winter months in cold climatic regions, sustains surface water flow beneath ice cover, which is essential for aquatic wildlife. Discharging groundwater also carries both essential nutrients and other geochemical constituents vital to sustaining aquatic ecosystems, but at the same time can also carry potential contaminants present within the groundwater system (Lewandowski et al., 2020).

One of the most essential, yet poorly understood roles of regional groundwater flow is the critical support it provides in sustaining Earth's fragile wetlands. Wetlands exist and are sustained in areas of continuous shallow water table conditions where the roots of phreatophytes, common in wetland environments, can access the required water supply from groundwater (Fig. 4). Lowering of water tables due to groundwater extraction activity or changing recharge conditions can result in serious and permanent damage to wetland features, in some cases causing their complete disappearance (Poeter et al., 2020; de Graaf et al., 2019).

Long-term depletion of global groundwater resources is also threatening the sustainability of irrigation practices worldwide (e.g., Scanlon et al., 2012). Attempts to mitigate these threats involve the intentional enhancement of groundwater recharge through a variety of approaches, including water harvesting. Redirection of runoff waters from impermeable surfaces or other drainage features to constructed infiltration basins facilitates soil water replenishment and groundwater recharge, augmenting subsurface water required to support the agricultural demand.

The progressive degradation of groundwater quality as a result of both natural and man-made contamination processes, as summarized above, represents another major threat to the long-term utility of this strategically-significant resource. For example, it

Fig. 4 Groundwater-surface interactions within a regional groundwater flow system showing surface water bodies under losing (Wetland A), flow-through (Lake B), and gaining conditions (Stream C). The hyporheic zone, a region of intense surface-groundwater mixing, is shown beneath Stream C.

is estimated that approximately 25% of all public supply wells in the United States produce groundwater that has concentrations of at least one contaminant of human health concern that is above the recommended drinking water limit (Toccalino and Hopple, 2010). As noted above, discharging groundwater with degraded water quality can also have serious impacts on the health of surface waters, wetlands, soils and associated ecological environments. The interaction between groundwater and surface water systems, under either recharging or discharging conditions, occurs at the terrestrial surface within the soil zone. The important role this shallow component of the Critical Zone plays in controlling the exchange of water and geochemical constituents between groundwater and surface water is explored in more detail in the next section.

Impact of soils on groundwater

Soil influence on groundwater recharge and flow

Water that percolates below the root zone and replenishes groundwater (i.e., reaches the water table) is termed groundwater recharge. A simple water budget expression for the soil zone can be used to estimate groundwater recharge as follows:

$$R = P + Q_{in} - ET - Q_{out} - \Delta S \quad (1)$$

where R is groundwater recharge, P is precipitation, ET is evapotranspiration, Q_{in} and Q_{out} are lateral flows of water into or out of the region of interest, respectively, in the form of surface or subsurface flows, and ΔS is the change in soil water storage. All components are expressed as rates, typically normalized to the area of interest (e.g., mm d^{-1}) but they can also be expressed as volumetric rates (e.g., $\text{m}^3 \text{d}^{-1}$).

The timing, magnitude and distribution of groundwater recharge varies considerably based on soil conditions, topography, vegetation, and climate, and the corresponding complex interplay between these different factors (Keese et al., 2005; Scanlon et al., 2006). Soil zone properties, including texture, structure and chemical or mineralogical composition, determine how water is partitioned between surface (runoff) and subsurface (infiltration) during precipitation events, affecting the amount of water in the soil zone available for potential groundwater recharge. A significant structural feature in most soil systems is macro-porosity, which refers to large continuous pores within the soil matrix normally formed by vegetation, soil fauna, desiccation or weathering after initial soil genesis. Preferential flow along soil macropore networks allows water to be rapidly transported vertically or laterally in the subsurface, bypassing the soil matrix, increasing the risk of groundwater contamination (Beven and Germann, 2013). Coarse-textured soils typically have greater infiltration capacity, making them more amenable to groundwater recharge, but preferential flow through macro-porosity in fine-grained soils can also lead to significant groundwater recharge. In agricultural settings, tillage practices and soil compaction from vehicular traffic can alter soil structure and macro-porosity, thereby affecting soil infiltration and drainage characteristics. The composition, structure and permeability of the native geologic materials underlying the soil zone will also impact groundwater recharge. Layers with little permeability in the vadose zone can result in perched water table conditions (isolated zones of water saturation above the regional water table), affecting subsurface flow patterns and rates of groundwater recharge.

Vegetation and land management conditions influence recharge potential in two main ways: (1) by altering soil infiltration characteristics, and (2) perhaps more importantly, they are a major control on ET losses from the soil zone which can limit groundwater recharge rates. Different land covers (e.g., vegetated vs. non-vegetated) or vegetation types will change ET rates, altering soil moisture conditions and the amount of water available for recharge (Keese et al., 2005). Vegetation is often closely linked with climate, which is another key control on groundwater recharge. Climate determines the amount, timing and type of precipitation inputs as well as the evapotranspirative demand, with recharge rates generally greater in humid climates than in arid or semi-arid regions. In many agricultural regions, irrigation inputs can further contribute to groundwater recharge. Due to interactions between various factors, the combination of climate and geologic conditions give rise to regions with similar ecological communities (termed ecoregions), physiography, or soil pedology that often share common recharge dynamics.

Topography drives groundwater flow systems, with groundwater recharge occurring in topographically higher areas and groundwater discharge in lower lying areas as described by Toth (1963), leading to the adage that the water table is considered a “subdued replica of topography” in many humid regions. However, groundwater flow patterns are complicated by undulations in topography and heterogeneous subsurface geologic formations, resulting in more complex local and regional flow systems (Fig. 5). Furthermore, climatic conditions can alter groundwater recharge patterns, particularly in more arid regions with seasonal precipitation or snow-melt dominated settings. In these regions, surface water runoff during rainy seasons or spring melt is shaped by topography and contributes to localized groundwater recharge beneath topographic lows (e.g., wadis, playas, wetlands). A classic example is depression-focused recharge, where snowmelt runoff from seasonally-frozen soils collects in topographic depressions and, following soil thaw in spring, results in groundwater recharge that varies both spatially and seasonally (Hayashi et al., 1998; van der Kamp and Hayashi, 1998).

Soil influence on groundwater quality

Water that migrates through the soil zone and recharges groundwater is subject to natural and anthropogenic influences that strongly influence groundwater quality. The soil zone is often referred to as a natural water filter and plays an important role in altering water quality through physical, geochemical, and biological processes. The physical filtration capacity of soil is determined by a range of soil characteristics, including porosity, pore geometry (e.g., size, shape, connectivity), structure, clay content, organic matter content, and soil particle physicochemical properties. Physical filtration is generally considered to be the removal of suspended colloidal or insoluble particles, including clay particles and microbes (e.g., viruses, bacteria, protozoa), during infiltration or percolation of water through the soil. Other mechanisms of filtration in partially saturated soils include pore straining, film straining, and surface deposition or adsorption. While these processes are generally effective at removing a large fraction of colloids (often >99%) in many soils, the importance of preferential flow in structured soils is increasingly being recognized as a critical pathway for colloidal (especially microbial) transport that can result in rapid movement of microbes to groundwater systems (Taylor et al., 2004).

Geochemical reactions in soil are an important attenuation mechanism for many dissolved groundwater contaminants of concern. Soils have charged particle surfaces that can transfer dissolved ionic species from solution in the process of sorption (attachment to the surface) and desorption (detachment from surfaces). Since most soils contain negatively charged surfaces, species such as Na^+ , Ca^{2+} , Mg^{2+} undergo cation exchange reactions that alter both soil properties and porewater solution compositions. Other solute species such as phosphate and many heavy metals are commonly attenuated by soil sorption, although the process can be reversible meaning that contaminant migration is slowed (termed retardation) but the contaminants are not completely removed and may be remobilized under certain conditions. Organic contaminants, including pesticides and petroleum hydrocarbons, are also subject to sorption and desorption processes that are largely controlled by the amount of organic matter in the soil profile. Reduction-oxidation (or redox) reactions in soil and groundwater are important in dictating the chemical composition of groundwater along a flow path. The natural exposure of soils to atmospheric oxygen means that soil porewater is initially oxidized (oxic). Recharge below the water table decreases or eliminates exposure to atmospheric oxygen, causing the water to eventually evolve to more reducing (or anoxic) conditions along the flow path. The persistence of dissolved oxygen (aerobic conditions), which is related to microbial activity, carbon availability and other biogeochemical factors, will affect groundwater redox conditions and, in turn, strongly influence other key redox sensitive elements like nitrogen, iron, manganese, and sulfur. The role of soil organic matter and denitrification in controlling groundwater nitrate concentrations is an excellent example of the important role that redox reactions play in the soil profile. Nitrate leaching from the soil zone is a major risk to groundwater in many agricultural landscapes, but denitrification of nitrate to N_2 gas can help to reduce nitrate loads and mitigate these risks. Thermodynamically, denitrification first requires the depletion of dissolved oxygen, which is often achieved through oxidation of dissolved organic carbon from the soil zone or other electron donors where present (e.g., sulfide oxidation).

The third main type of soil “filtering” process is biological, with organisms (predominantly micro-organisms) that proliferate in the soil zone responsible for the transformation or degradation of potential contaminants. Soil microbial communities are incredibly diverse and abundant, with global soil microbial biomass (expressed in terms of carbon mass) on the order of tens of billions of tonnes, equating to roughly 10^5 – 10^9 organisms cm^{-3} (Serna-Chavez et al., 2013; Magnabosco et al., 2018). The majority of microorganisms are present in the top meter or two of the soil profile, but they are adapted to survive in environments up to kilometers below the Earth’s surface (Magnabosco et al., 2018). Degradation of pollutants by microbes is termed biodegradation, and is important for the removal of a wide range of organic compounds, notably pesticides and petroleum hydrocarbons, from soil and groundwater systems. Potential contaminants are typically broken down into less toxic or non-toxic products by native

Fig. 5 Cross-sectional examples of groundwater flow systems demonstrating the important roles of (a) topography, (b) geologic heterogeneity, and (c) complex interaction between topography and geology in controlling subsurface groundwater flow patterns. K is the hydraulic conductivity. Delineation of characteristic local, intermediate, and regional groundwater flow systems are shown in the top diagram.

microbial communities that rely on the reactions as an energy source. Micro-organisms are also involved in transformation reactions of inorganic compounds and metals, with many geochemical reactions being microbially mediated. Key redox reactions, such as denitrification noted above, depend on natural microbial communities present in the subsurface to proceed. As such, the natural attenuation of potential contaminants offered by soils serves to protect underlying groundwater quality from degradation (Chamy and Rosenkranz, 2013).

Biogeochemical processes can also result in the introduction of pollutants to soil pore water and groundwater. Dissolution of chemical compounds naturally present in soil or underlying geologic materials will result in groundwater contamination if concentrations exceed an acceptable concentration limit (often related to drinking water or some other intended water use). A classic example is the extensive groundwater arsenic contamination that has been identified in regions such as Bangladesh, India, Mongolia, China, Argentina, United States and Mexico (Podgorski and Berg, 2020), but dissolution of natural contaminants such as nitrate, fluoride, asbestos and chromium has also been reported around the world. Redox and acid-base reactions in soil can exacerbate groundwater contamination. Carbon cycling in soils alters pore water chemistry via dissolution or degassing of atmospheric and plant-produced carbon dioxide, typically resulting in carbonic acid production that promotes weathering and dissolution. In soils or geologic materials with abundant sulfide minerals, sulfide oxidation can further acidify the soils resulting in the dissolution and mobilization of heavy metals to groundwater. This process is particularly noteworthy at mining sites, where it has attracted the term acid mine drainage (Nordstrom, 2011).

Sources of groundwater contamination typically originate from a wide range of natural and anthropogenic sources at the surface, which vary in spatial extent (e.g., point, non-point or diffuse, linear) and duration (e.g., one-time spill, continuous input). Diffuse sources with continuous loading can result in significant accumulation of contaminants stored in the vadose zone at a regional scale, which are then carried into groundwater during recharge events. Vadose zone and groundwater flow velocities are much slower than surface water flows, resulting in long residence times that can range from days to decades (or longer), depending on groundwater recharge rates. Consequently, long-term contaminant loadings, such as the buildup of soil nitrogen in agricultural watersheds, creates a legacy of contamination for a long time into the future. Given the long lag times, changes in land or water management practices implemented today could take long times (decades or longer) to achieve improvements in groundwater quality in the absence of other natural or engineered attenuation mechanisms (Rudolph et al., 2015).

Land management influence

Land management decisions shape the hydrological and geochemical function of soils in different settings, in turn affecting groundwater conditions. The starkest differentiation is between urban and rural soil environments, with noteworthy influences outlined further below.

Rural soil environments

Globally, agriculture land use comprises about 50% of the habitable land area (Ritchie and Roser, 2019). In these rural areas, agricultural and land management practices can dramatically alter the soil environment and the local water balance, ultimately influencing rates and timing of groundwater recharge. A global meta-study by Mohan et al. (2018) has shown that land use and vegetation (land cover) conditions, together with climatic factors (precipitation and ET) were the most important controls on groundwater recharge. Conversion of land to agricultural production in many regions of the world involves replacing deep-rooted perennial native vegetation (including forest or shrub lands) with shallow-rooted annual crops, reducing ET and consequently increasing groundwater recharge rates, in some instances by up to one or two orders of magnitude (Han et al., 2017; Scanlon et al., 2007). Similarly, changing cultivation practices, such as the conversion from perennial grasses to annual row crops or the adoption of certain tillage practices, can alter soil structure and affect soil water partitioning (infiltration-runoff-ET) during and after precipitation events, effectively increasing deep drainage and groundwater recharge potential. As noted earlier, soil compaction from agricultural vehicles can also significantly influence shallow soil characteristics and reduce infiltration capacity.

The combination of soil and climate conditions in a region often results in a pronounced seasonality to groundwater recharge. Using stable water isotope data from 54 locations around the world, Jasechko et al. (2014) showed a greater proportion of groundwater recharge over winter seasons in arid and temperate regions, and more recharge in wet seasons in tropical regions. The greater relative contribution of winter precipitation to groundwater recharge in arid and temperate regions can be attributed in part to reduced ET potential over winter. In addition, for snowmelt driven watersheds in higher latitude regions the proportion of winter recharge can increase further due to the rapid input of water during spring freshet when soils are still frozen, often resulting in depression-focused recharge described earlier. As one might intuitively expect, groundwater recharge in the tropics is driven largely by high-intensity rainfall events, occasionally following a similar depression-focused recharge behavior, and resulting in the largest proportion of annual recharge during the wet season.

Irrigation and drainage of agricultural lands both have important consequences for groundwater systems. Irrigation, which is essential for agricultural production in many arid and semi-arid regions, will affect underlying groundwater resources in different ways depending on the source of water used for irrigation. Where irrigation water is derived from local or imported surface water sources, enhanced groundwater recharge occurs. This is due to increased water inputs that result in drainage below the root zone, termed irrigation return flows, as well as water losses from irrigation canals and conveyance systems. If irrigation water is sourced from local groundwater systems, groundwater pumping will result in a decline in groundwater levels, which may or may not be offset by increased groundwater recharge rates associated with irrigation return flow. Normally in these situations, only a fraction of

the water pumped for irrigation is returned to the aquifer in the form of groundwater recharge, hence the net result of irrigation is a decline in groundwater levels. In more humid regions or agricultural areas with poorly draining soils, artificial subsurface drainage systems including mole drains and tile drains may be used to artificially lower the water table and promote more timely and effective access to a field for agricultural operations. Such artificial drainage of the landscape drastically alters both the surface and subsurface hydrologic flow patterns in a catchment, with important consequences for transport of any potential contaminants (Golmohammadi et al., 2017). In essence, shallow groundwater flows into the shallow drains and is rerouted horizontally via the interconnected drainage network to nearby surface water drainage pathways. In areas of natural groundwater recharge, this would theoretically reduce the rates of recharge and any potential groundwater contaminant loads. However, even though shallow enhanced drainage systems clearly alter the near-surface soil water balance, the corresponding influence on groundwater recharge rates and water quality is not fully understood and is still a topic of active research.

Agricultural land use in rural watersheds is often associated with the input of nutrients and agrichemicals to improve agricultural productivity, but these compounds can be leached through the soil profile and degrade groundwater quality. Organic (e.g., manure, compost) and inorganic fertilizer inputs in areas of more intensive agriculture result in the export of nitrogen (typically as nitrate), phosphate, chloride and other chemical constituents (e.g., Ca, Mg) to underlying groundwater systems. While it can be difficult to attribute groundwater nitrate contamination to specific sources owing to the complexities of soil N cycling, multiple N sources (e.g., manure, inorganic fertilizer, organic matter mineralization, atmospheric N₂ fixation), and subsurface attenuation mechanisms (e.g., denitrification), there is clear evidence that nitrate contamination at watershed scales is strongly correlated to agricultural land use (Böhlke, 2002). In contrast, pesticides (and their metabolites) are often detected in shallow groundwater, but concentrations tend to be low due to sorption and relatively rapid degradation in the soil profile. Enhanced groundwater recharge, whether due to land use alteration or irrigation, has also been shown to have important consequences for soil and groundwater salinization, which is described in more detail in the following section.

Urban soil environments

Paving and the proliferation of impervious surfaces in urban environments reduces the soil infiltration potential and increases stormwater runoff, suggesting a reduction in groundwater recharge potential. However, leakage from water distribution and sewer infrastructure networks provides additional sources of groundwater recharge and ET decreases due to the reduction in bare soil and vegetated surfaces. As a result, several studies have noted increased rates of groundwater recharge in urban settings (Lerner, 2002; Tubau et al., 2017) and corresponding changes in the spatial distribution of recharge are expected but less well documented.

Many municipalities are moving toward green stormwater infrastructure (GSI) and low-impact development technologies to better manage stormwater flows in the face of increasing urbanization and changing climate patterns. GSI essentially involves stormwater management approaches that rely on soil processes, notably infiltration, soil water storage and ET, to conserve or restore natural hydrological and ecological function in urban environments (Chini et al., 2017). Examples of GSI technologies include green roofs, bioswales and bioretention systems, rain gardens, and permeable pavements. Most GSI systems involve vegetated “green” spaces that store or infiltrate stormwater runoff collected from nearby impervious surfaces (e.g., roofs, parking lots, roadways), thereby reducing stormwater runoff volumes and improving water quality for downstream receptors. While GSI has many benefits, it is not yet clear what influence they would have on urban groundwater systems. Enhanced localized infiltration beneath GSI systems has the potential to increase groundwater recharge or induce lateral subsurface flow that could adversely impact other urban infrastructure (e.g., water inflows to basements), but there is little research to date on these potential concerns.

Urbanization brings with it the storage and utilization of a wide range of chemicals that can threaten groundwater supplies. Fertilizers and pesticides are routinely applied in urban landscapes, creating the same issues that arise in agricultural regions (see above). Commercial and industrial operations in urban centers have historically stored, utilized, or disposed of a wide range of potential contaminants, including underground fuel tanks, septic systems (nutrients, microbial contaminants), chlorinated and volatile organics, polyaromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and metals. Municipal wastes are frequently disposed of in landfills that become localized and concentrated sources of these same contaminants. In cold regions, the application of road salts to improve winter driving and pedestrian conditions leads to the accumulation of salts in soil and underlying groundwater. Similarly, PAHs originating from asphalt paved roadways or burning of hydrocarbon fuels can leach to groundwater. Water leakage from urban water distribution and sewer systems can become distributed linear sources of contamination, releasing water treatment byproducts (e.g., chloroform, nutrients, detergents and surfactants, pathogens) or other emerging contaminants (e.g., pharmaceuticals, microplastics, nanomaterials and per- and polyfluorinated substances (PFAS)) to the subsurface. Little is currently known about the capacity of soils to retain or remove many emerging contaminants, and when combined with typically long vadose zone and groundwater storage times described earlier, there is the potential for a legacy of future water quality concerns in these environments.

Groundwater impact on soils

Just as soils play an important role in influencing groundwater systems, groundwater conditions will similarly impact the soil zone through various interconnections and feedback mechanisms. One prime example of these feedback mechanisms is water table depth, which tends to be maintained within a certain range by interactions between the soil and groundwater zones. Increasing rates of groundwater recharge will tend to cause the water table to rise, which in turn can increase soil moisture due to capillary rise

above the water table. The increasing soil moisture will tend to result in greater rates of ET, thereby reducing the groundwater recharge potential and stabilizing the water table within a certain range below the ground surface. In the other direction, declining water tables can lower soil moisture conditions, reducing ET (and soil hydraulic conductivity), leading to a reduction in vertical water movement and limits on water table decline. In cold regions where soils freeze seasonally, subzero temperatures cause the formation of pore ice and a corresponding decrease in soil water potential (or increase in matric suction), in a process called cryosuction. The result is a vertical migration of soil moisture toward the freezing front from unfrozen soil below, which can create ice lenses, generate frost heaving, and cause freezing-induced declines in the water table.

Groundwater-based interactions between the water table, soil capillarity, and vegetation (i.e., ET demand) can also have important consequences for soil quality and agricultural productivity, primarily due to salinization and waterlogging of soils. As noted earlier, increased groundwater recharge due to land alteration or irrigation can raise the water table to near the surface, where capillarity and evapotranspiration combine to concentrate soluble salts in the soil zone. The increased soil salinity and poor drainage characteristics (i.e., waterlogging) associated with rising groundwater levels, which tend to be exacerbated in arid climates and low-lying areas, have degraded soil quality and agricultural productivity in large tracts of land across the globe (Han et al., 2017; Scanlon et al., 2007). In a similar way, natural groundwater discharge can alter soil conditions and result in the accumulation of salts and other minerals at Earth's surface. Groundwater discharge carries with it many dissolved compounds that can either (a) be discharged to surface water bodies, or (b) if ET exceeds the rate of groundwater discharge, be deposited by chemical precipitation in surficial soils. Soil pore water in many groundwater discharge areas is therefore often characterized by elevated levels of dissolved solids, resulting in localized zones of soil salinity, sodicity, and enrichment of minerals from geologic weathering (e.g., sulfur, iron, lithium) that can be both beneficial (e.g., mining, animal salt licks) and harmful (e.g., soil hardpans, saline soil degradation).

As part of the natural hydrologic cycle, groundwater discharge to the Earth's surface is important to many surficial systems. Groundwater discharge via seeps and springs provides baseflow that sustains flow in streams and rivers and water levels in lakes and wetlands. The shallow zone immediately around stream beds, where groundwater-surface interactions are more prevalent, is termed the hyporheic zone (Fig. 4) and is responsible for enhanced storage and exchange of water, thermal energy, nutrients, contaminants, and dissolved gases (oxygen) that are vitally important for riparian vegetation and aquatic organisms.

In recent years, there has been increasing recognition that groundwater plays a critical role in supporting aquatic and terrestrial ecosystems, providing valuable ecosystem services in a wide range of landscapes (Griebler and Avramov, 2015). The function of these groundwater-dependent ecosystems is often not fully understood, with groundwater contributions varying spatially (direct or indirect discharge, large or small area) and temporally (perpetual, seasonal, intermittent), and ecosystems influenced by both water quantity and quality. Groundwater dependent ecosystems and environmental flows in rivers and streams are at risk from excessive groundwater pumping, with global estimates indicating that approximately 42%–79% of watersheds with groundwater pumping are at risk of reaching environmentally sustainable stream flow limits by 2050 (de Graaf et al., 2019).

Subsurface geology, particularly the distribution of rock and sediment permeability, is one of the most important controls on groundwater flow, thus influencing the distribution, rate, and timing of groundwater discharge. Wetlands with groundwater dependent vegetation and hydric soils are typically situated in discharge areas at the end of subsurface flow paths that are largely determined by surface topography and subsurface geologic heterogeneity (USGS, 1996). For example, groundwater fed wetlands are often situated near topographic depressions or breaks in slope, where more permeable strata outcrop at surface, or above the downgradient end of laterally discontinuous aquifer units (Fig. 6). Flow pathways and landscape position will also affect the wetland hydroperiod, or the duration and portion of the year when inundated with water, thereby regulating soil formation and vegetation characteristics.

Conclusions

Soils play a critical and complex role in controlling the hydrologic, chemical, and biological interaction between the land surface and the underlying groundwater system, a region often referred to as the shallow Critical Zone. Many aspects of this interaction are poorly understood and require additional investigation and research. This has become particularly evident in light of the potential influence of climate warming. There is a dynamic synergy between how soil processes influence groundwater quantity and quality, and how shallow groundwater flow systems control soil water content, soil mineral and pore water composition, and soil ecologic capacity. The combined influence of rapid and extensive anthropogenic change and evolution within the hydrologic cycle as weather patterns change is leading to noticeable, yet highly unpredictable impacts within both the near-surface soil environment and the deeper subsurface groundwater regime.

As urbanization continues, groundwater extraction increases, and agricultural land management expands, groundwater recharge and the critical soil processes that sustain it are changing. In some areas, this is resulting in reductions in groundwater replenishment and deterioration of groundwater and soil quality. The capacity for the soil system to function as a natural filter, protecting subsurface water from contaminant migration, is beginning to decline as the reactive capacity of the soils progressively decrease through the long-term exposure to various chemical species. This is already having profound effects on groundwater quality as infiltrating contaminant mass builds up in the soil zone. The chronic concentration of minerals in the shallow soil system due to the combined effects of mineralized groundwater discharge and evapotranspiration is leading to soil degradation including extensive soil salinity. The potential interactive processes within the soil profile related to emerging contaminants such as microplastics and nanoparticles, however, remain largely unknown.

The storage capacity and ability of the soil profile and vadose zone to control infiltration rates and vertical pore water mobility through processes related to partially saturated flow conditions and capillarity are crucial in preserving water within the subsurface environment. These processes are also fundamentally important in providing required chemical and biological reaction times necessary to naturally attenuate chemicals and pathogens before they reach groundwater. Anthropogenic modifications to the water cycle through the introduction of artificial subsurface drainage systems (e.g., tiles and mole drains) and irrigation can have profound impacts on these processes by altering soil characteristics, pore water content and quality, groundwater recharge and the nature of the interaction between shallow groundwater and surface water bodies. As agricultural water demands increase and water management strategies designed to maximize food production become more necessary, soil and groundwater conditions within the rural setting are likely to continue to degrade globally.

The incorporation of relevant soil processes and soil-groundwater interaction into studies of groundwater resource management and sustainability will be essential when considering either anthropogenic or ecological applications. This will be particularly true when employing models designed to predict soil, hydrologic, and ecosystem responses under rapidly changing climatic conditions. In many cases, these processes are still poorly understood and rapidly evolving and represent an area of critical future research.

Abstract

Temperature dependence of soil hydraulic properties is typically accounted for by the so-called surface tension-viscous flow (STVF) theory, considering changing soil water properties only. However, there remains much uncertainty on temperature effects, as most reported research has been through laboratory experimentation on small soil cores using different methodologies for a limited range of soil types. Though effects of soil water properties can be measured accurately to verify the STVF theory, significant deviations are often reported, especially to quantify temperature dependence of the soil unsaturated hydraulic conductivity. In part, this is explained by soil temperature changing soil particle-soil solution interactions, as well as the soil's entrapped air and water volumes affecting pore connectivity and water retention.

Key points

- Effect of temperature on soil water properties is largely determined by changing water viscosity and surface tension (STVF theory).
- Full understanding of the temperature effects on soil hydraulic properties is incomplete because research has been limited to controlled laboratory studies, rather than in-situ field investigations.
- Temperature effects on field soil hydrology are especially relevant because of global warming implications.

Nomenclature

$\alpha_h(T)$	Temperature scaling factor of soil water retention curve (–)
$\alpha_K(T)$	Temperature scaling factor of hydraulic conductivity (–)
β	Conductivity parameter (–)
θ	Volumetric water content ($\text{m}^3 \text{m}^{-3}$)
θ_s	Saturated volumetric water content ($\text{m}^3 \text{m}^{-3}$)
θ_r	Residual volumetric water content ($\text{m}^3 \text{m}^{-3}$)
σ	Surface tension of water (Nm^{-1})
γ	Contact angle (degree)
ρ	Is the density of water (kg m^{-3})
l	Tortuosity parameter (–)
η	Connectivity parameter (–)
μ	Dynamic viscosity of water (N s m^{-2})
ν	Kinematic viscosity (m^2/s)
h_m	Soil water matric potential or matric pressure head, (m)
k	Intrinsic soil permeability (m^2)
g	Acceleration due to gravity (9.8 m s^{-2}).
C	Soil water capacity (m^{-1})
$D(\theta)$	Soil water diffusivity (m^2/s)
K	Soil unsaturated hydraulic conductivity (m s^{-1})
K_s	Saturated hydraulic conductivity (m s^{-1})

q_w	Darcy flux density (m s^{-1}),
S_e	Effective soil saturation (–)
T_r	Reference soil temperature ($^{\circ}\text{C}$)
z	Vertical soil position ($z > 0$, upwards, m)

Introduction

Soil temperature has a range of impacts on soil hydraulic behavior, driven primarily by the temperature dependence of the surface tension and viscosity of pore water. Improved understanding of temperature effects on soils will become increasingly relevant as climatic changes are likely affecting soil hydrologic processes with temperature increasing globally thereby altering both natural and agricultural ecosystems in ways yet to be determined.

Diurnal fluxes in soil water with depth are an example of temperature effects, driven by surface temperature changes that cause water to move from warmer to colder regions. Vapor phase transport is also influenced by the impact of temperature on the vapor pressure of water, described in the Heat and Water Transfer article.

Using physical principles as outlined below, unsaturated soil water flow is largely controlled by the physical arrangement of soil particles in relation to the water and air phases within the soil's pore space, as determined by pore size distribution and water-filled porosity or volumetric water content, θ (m^3 water/ m^3 bulk soil). In addition to θ , the volume of water is sometimes defined by degree of saturation, $S = \theta/\theta_s$, or effective saturation (S_e) as defined by

$$S_e = \frac{\theta - \theta_r}{\theta_s - \theta_r} \quad (1)$$

normalizing the mobile water between values of zero and one, while defining a residual water content, θ_r , for water that is considered immobile.

When considering temperature effects on the soil hydraulic properties, we will distinguish between soil water solution properties and soil-water interactions with other mechanisms that affect soil structure, pore geometry and pore connectivity. Temperature dependence of soil water properties only is determined by the so-called surface tension-viscous flow (STVF) theory.

Soil water retention

The soil-water retention function describes the relationship between the volumetric water content retained in soil, θ , and the soil capillary and adsorptive forces. It is also known as the soil-water release or soil-water characteristic function. These two water-retaining forces in unsaturated soils combined are defined as the matric forces and are sometimes also called suction forces. These suction forces increase as the size of the water-filled pores decreases, such as occurs by drainage, root water uptake or soil evaporation. When expressed relative to the reference potential of free water, the water potential in unsaturated soils is negative (the soil-water potential is less than the water potential of free water at atmospheric pressure). It is often referred to as the soil water matric potential. Hence, the matric potential decreases or becomes more negative as the soil water content decreases. In soils, water potential is usually expressed with respect to a unit volume of water, thereby attaining units of pressure (Pa) or per unit weight of water, so that the potential represents the equivalent height of a column of water (m). The pressure head equivalent of the combined adsorptive and capillary forces is defined as the matric pressure head, h_m . Since the matric forces are controlled by pore size distribution, specific surface area, and type of physico-chemical interactions at the solid-liquid interfaces, the soil water retention curve is soil-specific.

By way of the unique relationship between capillary water pressure and the radius of curvature of the air-water interface, and using the analogy between capillary tubes and the irregular pores in porous media, a relationship can be derived between h_m and its corresponding effective pore radius, r_e , or

$$|h_m| = \frac{2\sigma\cos\gamma}{\rho g r_e} \quad (2)$$

where σ and γ are defined as the surface tension and wetting angle (of wetting fluid with solid surface), respectively, ρ is the density of water, and g is the acceleration due to gravity (9.8 m s^{-2}). This capillary equation simplifies to $|h_m| = 0.15/r_e$, when both h_m and r_e are expressed in cm, for fully hydrophilic soils, as the surface tension is assumed to apply for pure water at room temperature. Moreover, in most studies of soil water flow and transport, isothermal soil conditions are assumed, ignoring the temperature dependency of the water parameters in Eq. (2).

However, in field conditions soil temperature is a dynamic variable that changes with both time and soil depth, so that soil and water parameters entering in Eq. (2) should be corrected for temperature changes. Whereas temperature effects on water properties such as surface tension and density are well defined, experimental confirmation of theoretical temperature effects on the soil water

retention are limited. Philip and de Vries (1957) were among the first to account for temperature effects on water properties, which was adapted by Hopmans and Dane (1986a) in their experimental work by relating the matric head at temperature T ($^{\circ}\text{C}$) to its corresponding value at a reference temperature, T_r , by a scaling factor $\alpha_h(T)$, or

$$h_m(T) = \alpha_h(T) \cdot h_m(T_r) \quad (3a)$$

where,

$$\alpha_h(T) = \frac{\left(\frac{\sigma}{\rho}\right)_T}{\left(\frac{\sigma}{\rho}\right)_{T_r}}, \quad (3b)$$

with $\alpha_h(T)$ decreasing as $T > T_r$. In addition to this work, others followed to validate such a theoretical correction, confirming that such correction for water properties is largely inadequate to account for temperature effects on the soil water retention curve. To explain the observed temperature effect discrepancies, Hopmans and Dane (1986b) investigated contributions of changing entrapped air volumes with temperature, whereas Nimmo and Miller (1986) suggested that solute concentrations of main organic substances decreased the surface tension of soil solution as compared to pure water, thereby affecting its temperature dependence differently. Later, Liu and Dane (1993) accounted for additional temperature effects by considering entrapped water pockets that transition to continuous soil water as temperature is increased. Experiments by Bachmann et al. (2001) were able to largely explain deviations because of significant changes in contact angle with temperature, and that therefore temperature effects were soil-specific. The hypothesis was confirmed by Joshi et al. (2019) from experiments using three different-textured soils.

Defining the soil water capacity as slope of the soil water retention curve by $C(h_m) = d\theta/dh_m$, one can derive that

$$C_T(h_m) = \frac{C(h_m, T_r)}{\alpha_h(T)}. \quad (4)$$

Unsaturated hydraulic conductivity

The relationship between the soil's unsaturated hydraulic conductivity, K , and volumetric water content, θ , is the other essential fundamental soil hydraulic property needed to describe soil water movement. It is also a function of the water and soil matrix properties, and determines water infiltration, evaporation and drainage rates, and is strongly affected by soil water content. It is defined by Darcy's equation, which relates the soil water flux to the total driving force for flow. Applying Darcy's law in the vertical dimension only, the magnitude of flow can be computed from the steady state flow equation (Darcy's law):

$$q_w = -K(\theta) \left(\frac{\partial h_m}{\partial z} + 1 \right), \quad (5)$$

where q_w is the Darcy volume flux density (m s^{-1}), z is vertical position ($z > 0$, upwards, m), and $K(\theta)$ denotes the unsaturated hydraulic conductivity (m s^{-1}). In this expression, the unsaturated hydraulic conductivity is related to the intrinsic soil permeability, k (m^2), by

$$K = \frac{\rho g k}{\mu} = \frac{g k}{\nu}, \quad (6)$$

where μ denotes the dynamic viscosity of water (N s m^{-2}), ν is the kinematic viscosity (m^2/s), and ρ and g are as defined before. The usage of permeability instead of conductivity allows application of the flow equation to fluids other than water with different density and viscosity values as k is defined as being a soils property only, independent of the transmitting fluid.

Soil hydraulic conductivity is typically assumed to be independent of temperature, yet from Eq. (6), it is now clear that ν is very much a temperature dependent parameter. Theoretical predications of temperature-dependent K have only accounted for temperature effects on ν , e.g., by defining a scaling factor $\alpha_K(T)$, or

$$K(T) = \alpha_K(T) \cdot K(T_r), \quad (7)$$

where $\alpha_K(T) = \frac{\nu_r}{\nu}$ and is increasing as $T > T_r$. This arises because the temperature sensitivity for μ is much larger than for ρ for liquid fluids. The relative magnitudes of $\alpha_K(T)$ versus $\alpha_h(T)$ using the STVF theory are presented in Fig. 1, and clearly show that predicted soil water retention effects of temperature are relatively small compared with the hydraulic conductivity effects, the latter being several times larger.

Most experimental $K(\theta, T)$ measurements typically find that observed effects are two to five times larger than those predicted by the STVF theory (Hopmans and Dane, 1986a; Constantz, 1982; Joshi et al., 2019). In part, this could be explained because of changing soil structure and pore characteristics by temperature, affecting the intrinsic permeability k in Eq. (6), as suggested by Gao and Shao (2015) and Kelishadi et al. (2018). Other possible reasons for the increased temperature effect could be explained by (a) changes in entrapped air volume, (b) a temperature coefficient of viscosity that is affected by pore water solutes, and (3) by vapor transport and enhanced liquid water flow, driven by imposed temperature gradients at relatively small soil water content values.

Fig. 1 Effect of temperature on soil water properties, as defined by temperature scaling factors $\alpha_h(T)$ and $\alpha_K(T)$, using the SFVF theory, with $T_r = 20^\circ\text{C}$ (Eqs. (3b) and (7), respectively).

Alternatively, when considering the temperature effects on $K(h)$, one finds these to be limited. This is so because the temperature effects on surface tension and viscosity are counteracting (Hopmans and Dane, 1986a) and offsetting each other.

Functional models for unsaturated hydraulic conductivity are based on pore size distribution, pore geometry and connectivity, and require integration of the soil water retention functions to obtain analytical expressions for the unsaturated hydraulic conductivity (Mualem, 1976). The resulting expressions relate the relative hydraulic conductivity, K_r , defined as the ratio of the unsaturated hydraulic conductivity, K , and the saturated hydraulic conductivity, K_s , to the effective saturation, and can be written in the following generalized form

$$K_r(S_e) = S_e^l \left[\frac{\int_0^{S_e} |h_m|^{-\eta} dS_e}{\int_0^1 |h_m|^{-\eta} dS_e} \right]^\beta \quad (8)$$

where l and η are parameters related to the tortuosity and connectivity of the soil pores, and the value of the parameter β is determined by the method of evaluating the effective pore radii. The moisture-dependency is highly nonlinear, with a decrease in K of 4–5 or more orders of magnitude within field-representative changes in water content. Model fitting techniques assume a prescribed form for the soil water retention curve, to be substituted in Eq. (8).

The ratio of the unsaturated K with the water capacity (C) is defined as the soil water diffusivity, $D(\theta)$, with dimension of m^2/s , or $D(\theta) = K(\theta)dh_m/d\theta = K(\theta)/C(\theta)$. The concept of diffusivity arises from a combination of Darcy law with the mass balance equation, when expressed in water content rather than soil water matric potential. Using Eqs. (3a) and (7), one can derive that the temperature effect on $D(\theta)$ can be computed from:

$$D_T(\theta) = K_T(\theta)/C_T(\theta, h_m) = \alpha_h(T_r) \alpha_K(T_r) * D(\theta, T_r), \quad (9)$$

indicating that the temperature effects are partly offset. However, since the temperature effect on $\alpha_K(T)$ is mostly dominating (Fig. 1), soil water diffusivity typically increases with temperature and may be dominated by temperature-induced changes in soil pore characteristics (Gao and Shao, 2015), thereby changing the intrinsic soil permeability in Eq. (6).

Unsaturated soil water flow modeling

Since the Darcy equation is strictly defined for steady state water flow conditions, the mass conservation principle is applied and combined with Eq. (5) to yield the so-called Richardson-Richards equation to solve for temporal changes in h_m or θ , at any depth z and time t :

$$\frac{\partial \theta}{\partial t} = C(h_m) \frac{\partial h_m}{\partial t} = \frac{\partial}{\partial z} \left[K(h_m) \left(\frac{\partial h_m}{\partial z} + 1 \right) \right], \quad (10)$$

and is valid for isotropic and isothermal conditions. With dynamic soil temperatures, the soil hydraulic parameters must be adjusted for temperature through the temperature corrections above, such as demonstrated by Hopmans and Dane (1985). However, in addition Philip and de Vries (1957) showed that additional water flow occurs through (a) liquid water flow by

temperature gradients and (b) vapor water transport occurring by both matric potential and temperature gradients. This requires that both the water and heat flow must be considered through their coupled transport equations, with transport coefficients defined by a total of four diffusivity coefficients, accounting for both liquid and vapor transport by matric potential gradients as well as by soil temperature gradients (see Heat and Water Transfer article to learn more about vapor transport). The complete expressions to define the coupled water and heat transport are extensive and include the need to quantify temperature effects on soil thermal properties (e.g., Hopmans and Dane, 1986c). For that reason, we refer to both Philip and de Vries (1957) and more recent work by Nassar and Horton (1992).

Long-term implications

Implications of diurnal soil temperature fluctuations and long-term temperature changes are extensive. As an example of diurnal variations, we demonstrate the effect of diurnal soil temperature variations on soil water infiltration with time in Fig. 2a, as presented by Jaynes (1990). The synchronized response is likely a direct consequence of changes in surface tension and viscosity with temperature (STVF theory). The modeling study by Jungqvist et al. (2014) showed that air temperature could increase more rapidly than soil temperature across the climatic gradient of Sweden (Fig. 2b), and indicated possible long-term impacts could be a shift in biomes from middle-boreal to southern-boreal in the northern most region of the country.

Assessment of temperature effects on soil properties has been done mostly in laboratory settings, allowing for testing of the STVF theory. Although such experiments allow for correction of unsaturated flow processes such as infiltration, drainage and consequences on soil water storage and plant available water on the short term (diurnal and seasonal), increasingly more relevant implications could be ascertained resulting from rising air and soil temperatures over the long-term by climate change. This includes soil water evaporation, soil water storage, plant-available water, and groundwater recharge, while other implications such as soil carbon stock, GHG emissions and soil thawing are intricately related to soil hydraulic properties. Therefore, the remaining discussion will focus only on consequences of increasing soil temperatures.

Detailed analysis of increased temperature on soil water retention shows that soil water storage and plant-available is reduced. This can be readily shown from the STVF theory, because of lowered surface tension and viscosity of water that decreases the soil's field capacity. Though relatively minor, together with the increased soil water evaporation, it is projected that most climatic regions will experience increasing risks of plant water stress and drought. Soil water evaporation will be enhanced by increasing air temperatures and vapor pressure deficits, coupled with changing soil water and soil vapor diffusivity values. In concert, as suggested by Green et al. (2019), the soil carbon stock is likely to decrease as climate warming continues, and much of the affected land surface may transition from a carbon sink to a carbon source in the future, thereby accelerating climate change.

Further implications of global warming come from the thawing of permafrost. Permafrost soils stay frozen for two or more years, often below a shallow layer of surface soil that freezes and thaws every year. Often the permafrost contains large amounts of organic matter that decomposes when thawed thereby emitting CO₂ in the atmosphere. Many permafrost soils are found in boreal forests that are potentially very productive and contain many wetlands because of the seasonal freezing and thawing. Understanding the implications of warming of these permafrost areas requires knowledge of their hydrologic behavior, largely controlled by soil hydraulic properties during and between freezing/thawing cycles. There is limited information available as their measurement in such conditions is extremely difficult, as complications arise because of soil structural changes by expansion of soils because of soil freezing, largely impacting soil water retention and hydraulic conductivity.

Fig. 2 (a) Effect of diurnal changes of soil temperature on soil infiltration (symbols are measured values and the solid curve is derived from temperature influence on water viscosity, from Jaynes, 1990), and (b) projected change in long-term annual air and soil temperature (20 cm depth) for various biomes across Sweden (Fig. 7 of Jungqvist et al.).

Summary

In brief, there remains much uncertainty on the temperature dependence of soil hydraulic properties. Much of the uncertainty arises because reported research has been through laboratory experimentation on small soil cores using different methodologies for a limited range of soil types. Though effects of soil water properties can be measured accurately to verify the STVF theory, significant deviations are often reported, especially to quantify temperature dependence of the soil unsaturated hydraulic conductivity. In part, this is explained by soil temperature changing soil particle-soil solution interactions because of soil solution chemistry as well as by changing soil pore connectivity and water retention as entrapped air and water volumes contract and expand (or change).

Increasingly, both water scarcity and climatic changes are making large fractions of continental populations vulnerable. Both are global issues that require attention to scientific agendas and policymakers, and for which mitigating soil and water management practices at local scales are crucial, to offset impacts of increasing temperatures globally. Therefore, future research should focus on the monitoring and analysis of in situ field-based experiments, especially with increasing scientific interest on the effects of global warming on soil water availability, drought and water security, and the need to include temperature-dependent soil physical characteristics in land surface simulation models that couple water and energy transfer between vegetated soils and the atmosphere above.

Abstract

Heat and water transfer in soils are governed by equations that correspond to heat and mass conservation. These soil physics equations deal with fluxes and storage of heat and mass (liquid water, water vapor) within soil. The theory has many useful applications, for example, soil temperature variations that affect crop production, water irrigation management, water vapor release to the atmosphere, ground heat exchange systems in commercial and housing areas, land surface modeling of surface temperature, fate and transfer of volatile organic compounds, and modeling of greenhouse gas emissions. The macroscopic scale mechanisms driving heat and mass fluxes described in this Chapter indicate the current knowledge used to interpret observations, and also expose the limitations of existing models. A pore-scale model is also briefly described which represents the fundamental mechanisms (microscopic scale) more precisely than the currently used representative elementary volume continuum models (macroscopic scale).

Key points

- Describe the mechanisms driving liquid, water vapor and heat flux in the soil
- Present the heat and mass transfer governing equations that can describe soil moisture content and temperature distributions in the soil
- Describe applications of the equations and possible future improvements

Nomenclature

q_L	Liquid water flux ($kg \cdot m^{-2} \cdot s^{-1}$)
ψ_m	Soil water matric potential (m)
K	Hydraulic conductivity ($m \cdot s^{-1}$)
z	Vertical axis (m) and it is oriented positively upward
ρ_L	Liquid water density ($kg \cdot m^{-3}$)
i	A unit vector with value that could be either +1 or – 1 for vertically upward or downward, respectively.
D_{TL}	Thermal liquid diffusivity ($K \frac{\partial \psi_m}{\partial T}$, $m^2 \cdot s^{-1} \cdot K^{-1}$)
T	Soil temperature (K)
q_v	Water vapor flux ($kg \cdot m^{-2} \cdot s^{-1}$)
D	Water vapor diffusion ($m^2 \cdot s^{-1}$)
Ω	Tortuosity factor (dimensionless)
θ_a	Volumetric air content ($m^3 \cdot m^{-3}$)
ρ_v	Water vapor density ($\rho_s h_r = \rho_s h_m$, $kg \cdot m^{-3}$). The ρ_s is saturated water vapor density ($kg \cdot m^{-3}$), h_r is relative humidity (dimensionless), and h_m is matric potential effect on relative humidity (dimensionless)
D_{mv}	Isothermal vapor diffusivity ($\frac{D\Omega\theta_a\rho_s}{\rho_L} \frac{\partial h_m}{\partial \psi_m}$, $m \cdot s^{-1}$)
D_{Tv}	Thermal vapor diffusivity ($\eta \frac{D\Omega\theta_a}{\rho_L} \left(h_m \frac{\partial \rho_s}{\partial T} + \rho_s \frac{\partial h_m}{\partial T} \right)$, $m^2 \cdot s^{-1} \cdot K^{-1}$), where η is vapor enhancement factor (dimensionless)
θ	Total water content ($m^3 \cdot m^{-3}$)
t	Time in second

θ_L	Volumetric water content ($m^3 \cdot m^{-3}$)
q_h	Energy heat flux ($J \cdot m^{-2} \cdot s^{-1}$)
λ_*	Thermal conductivity of wet porous medium ($W \cdot m^{-1} \cdot K^{-1}$)
L_o	Latent heat of vaporization ($J \cdot kg^{-1}$) at T_o
c_v	Specific heat of water vapor ($J \cdot kg^{-1} \cdot K^{-1}$)
T_o	An arbitrary reference temperature (K)
c_L	Specific heat of liquid water ($J \cdot kg^{-1} \cdot K^{-1}$)
S_h	Total heat content ($J \cdot m^{-3}$)
C_d	Volumetric heat capacity of dry soil solid matrix including the organic matter ($\rho_b(c_o\phi_o + c_m\phi_m)$, $J \cdot m^{-3} \cdot K^{-1}$). The ρ_b is soil bulk density ($kg \cdot m^{-3}$), c_o is specific heat of organic matter ($J \cdot kg^{-1} \cdot K^{-1}$), ϕ_o is organic mass fraction (dimensionless), c_m is specific heat of soil minerals ($J \cdot kg^{-1} \cdot K^{-1}$), and ϕ_m is mineral mass fraction (dimensionless)
W	Differential heat of wetting ($J \cdot kg^{-1}$)
$L(T)$	Latent heat of vaporization ($J \cdot kg^{-1}$) at T
$Q_b(h)$	Bond invasion potential ($N \cdot m^{-2}$)
γ	Surface tension ($N \cdot m^{-1}$)
P_g	Gas pressure ($N \cdot m^{-2}$)
$P_l(h)$	Liquid pressure ($N \cdot m^{-2}$) at elevation h oriented vertically positively downward
$\Delta\rho$	Density difference between two fluids ($kg \cdot m^{-3}$)
r_b	Throat radius (m)
g	Gravity acceleration ($m \cdot s^{-2}$)
L	Vertical height of model medium (m)
B	Bond number (dimensionless)

Introduction

Soil water is vital for sustaining life in terrestrial environments. Soil water may come from sources such as precipitation and upward movement of groundwater, or by human interventions with inputs such as irrigation. A consistent soil water supply to support plant root adsorption and transpiration is necessary to sustain crop productivity. In both cropped and natural systems, soil water is transferred back to the atmosphere through a combination of evaporation and transpiration. These processes tightly connect the terrestrial hydrologic cycle (mass transfer) to the land-surface energy balance (heat transfer). Soil water is in a cycle of continuous exchange with its surroundings according to gradients in water potential and temperature. Through these exchanges, soil water storage can vary between extremely dry and saturation. Since soil water dynamics are governed by both mass and heat mechanisms, accounting for these mechanisms makes possible forecasting and scenario testing, and enhances decision-making strategies for allocating water resources.

Because soil water is a key variable that exerts control on a range of environmental processes, understanding mechanisms that drive its redistribution is broadly important to a range of problems in agriculture, engineering, and environmental sciences. Some problems can be addressed without considering the full complexity of these mechanisms. Mass transfer of soil water modeled by the Richardson-Richards equation often excludes vapor transfer. As soil temperature gradients become pronounced, water vapor mechanisms are included in the mass transfer model. Heat transfer within soil is often simplified to conduction and modeled by Fourier's law. When phase transition and fluid mass transfer cannot be neglected, latent heat of vaporization, and sensible heat transfer mechanisms of vapor and liquid water are included in the heat transfer equation. An effort at simplification may include decoupling and solving the heat and mass transfer equations separately. Alternatively, continued growth in our understanding of the complexity in water and heat transfer mechanisms can provide useful insights to address new and emerging challenges, such as global climate change and uncertainty. Our capacity to address new problems is supported by our ability to extrapolate relationships from basic mechanisms. In the following sections, we present macroscopic, continuum-based theory for mechanisms driving water movement and heat transfer, we briefly introduce a pore-scale model, and we discuss applications and limitations to existing theory.

Mechanisms for transport of liquid and water vapor in soil

Water flux in unsaturated soil is described by the Buckingham-Darcy equation,

$$q_L = -\rho_L K \frac{d\Psi_m}{dz} - \rho_L Ki \quad (1)$$

The left term is taken as the mass of water moving through a unit cross-sectional area in a unit of time. Eq. (1) assumes that water density does not change with space (z), and its Cartesian coordinate is aligned vertically upward positive. The first term on the right

is the water flux rate due to the matric potential gradient, which represents water flow from higher to lower potential regions. The negative sign on the term is to cancel the negative value in the denominator (dz). The second term on the right represents the gravity water flux, and the negative sign indicates gravity water flux is oriented upward.

Under the influence of temperature, Eq. (1) can be extended to account for a temperature gradient-driven flux (Milly, 1982),

$$q_L = -\rho_L K \frac{d\Psi_m}{dz} - \rho_L D_{TL} \frac{dT}{dz} - \rho_L Ki \quad (2)$$

The second term on the right is the water flux due to a temperature gradient, which is water transfer from higher to lower temperature regions. The term can be neglected when there is a homogenous temperature, i.e., spatially uniform temperature. Hydraulic conductivity is also influenced by soil temperature (Hopmans and Horton, 2022).

In addition, there is a water vapor flux in unsaturated soil. The vapor flux is often described by Fick's law,

$$q_v = -D\Omega\theta_a \frac{d\rho_v}{dz} \quad (3)$$

The equation is taken as the mass of vapor transfer in a unit cross-sectional area in a unit time. The equation describes water vapor movement from high to low vapor density regions. The water vapor transport occurs only in the pore space corresponding to the volumetric air content. The travel distance of the water vapor in the soil increases as it moves around and over the soil particles, liquid films, and pore water as given by a tortuosity factor. These two parameters reduce the water vapor flux in soil compared to that in open air space.

The fundamental independent variables driving water vapor flux in the soil are temperature and matric potential. Hence, Eq. (3) can be expanded as below,

$$q_v = -\rho_L D_{mv} \frac{d\Psi_m}{dz} - \rho_L D_{Tv} \frac{dT}{dz} \quad (4)$$

The first term on the right side of the equation represents the matric potential gradient driven water vapor flux from higher to lower pressure regions, and the second term represents the temperature gradient driven water vapor flux from higher to lower temperature regions.

The combined liquid water and water vapor fluxes give a total mass flux in the soil, as

$$\frac{q_L + q_v}{\rho_L} = -(K + D_{mv}) \frac{d\Psi_m}{dz} - (D_{TL} + D_{Tv}) \frac{dT}{dz} - Ki \quad (5)$$

The governing equation for liquid and water vapor

The mass conservation of liquid water and water vapor in the soil in the vertical spatial dimension is given by,

$$\frac{\partial(\rho_L \theta)}{\partial t} = -\frac{\partial(q_L + q_v)}{\partial z} \quad (6)$$

The variable $\rho_L \theta$ in the storage term is given by the mass of liquid water and water vapor in a unit volume of the soil. By placing Eq. (5) and $\rho_L \theta = \rho_L \theta_L + \rho_v \theta_a$ into Eq. (6) and assuming water density does not change with time, Eq. (6) can be rewritten as,

$$\frac{\partial\left(\theta_L + \frac{\rho_v}{\rho_L} \theta_a\right)}{\partial t} = -\frac{1}{\rho_L} \frac{\partial\left(-\rho_L(K + D_{mv}) \frac{\partial\Psi_m}{\partial z} - \rho_L(D_{TL} + D_{Tv}) \frac{\partial T}{\partial z} - \rho_L Ki\right)}{\partial z} \quad (7)$$

Also, assuming that liquid water density does not change with space, the equation becomes,

$$\frac{\partial\theta_L}{\partial t} + \frac{1}{\rho_L} \frac{\partial}{\partial t}(\rho_v \theta_a) = \frac{\partial}{\partial z} \left[(K + D_{mv}) \frac{\partial\Psi_m}{\partial z} + (D_{TL} + D_{Tv}) \frac{\partial T}{\partial z} + Ki \right] \quad (8)$$

The water vapor density is a function of matric potential and temperature, and the volumetric air content is a function of total porosity and volumetric water content. The matric potential is related to the soil moisture content by a water retention function. The model further assumes that the total porosity does not change with time. Using the chain rule method, the second term on the left side of Eq. (8) can be expanded into (Heitman et al., 2008a),

$$\left(1 + \frac{\theta_a}{\rho_L} \frac{\partial\rho_v}{\partial\Psi_m} \frac{\partial\Psi_m}{\partial\theta_L} - \frac{\rho_v}{\rho_L}\right) \frac{\partial\theta_L}{\partial t} + \frac{\theta_a}{\rho_L} \frac{\partial\rho_v}{\partial T} \frac{\partial T}{\partial t} = \frac{\partial}{\partial z} \left[(K + D_{mv}) \frac{\partial\Psi_m}{\partial z} + (D_{TL} + D_{Tv}) \frac{\partial T}{\partial z} + Ki \right] \quad (9)$$

The right side of Eq. (9) indicates the mass flux resulting from the matric potential gradients, the temperature gradients, and gravity. Both the matric potential and temperature gradients are imposed on the mass transport of liquid water and water vapor, whereas gravity is only applied to liquid water. The mass fluxes result in the time-varied soil moisture content and soil temperature, as indicated in the left side of Eq. (9).

Mechanisms driving heat transfer

Heat flux in unsaturated soil is given by (de Vries, 1958),

$$q_h = -\lambda_* \frac{dT}{dz} + L_o q_v + c_v(T - T_o)q_v + c_L(T - T_o)q_L \quad (10)$$

The left side of the equation is taken as the heat energy that moves across a unit cross-sectional area in a unit of time. The first term on the right is heat conduction in soil. The second term is the heat transfer by water vapor movement from the latent heat of vaporization. The last two terms are heat transfers by sensible heat movement due to water vapor and liquid water fluxes, respectively. Eq. (10) does not include the sensible heat movement by water transfer in plant roots.

The governing equation for heat transfer

Heat energy conservation is given by,

$$\frac{\partial S_h}{\partial t} = -\frac{\partial q_h}{\partial z} \quad (11)$$

The equation indicates the flux of heat energy in the vertical spatial dimension on the equation right side, which results in the change in the heat storage with time on the equation left side. If the incoming heat flux is greater than the outgoing heat flux, the heat storage will increase, and vice versa.

Heat storage in the soil is given by (de Vries, 1958),

$$S_h = C_d(T - T_o) + c_v \rho_v \theta_a(T - T_o) + c_L \rho_L \theta_L(T - T_o) + L_o \rho_v \theta_a - \rho_L \int_{t_o}^t W \frac{\partial \theta_L}{\partial t} dt \quad (12)$$

The first term on the right is the heat storage in the soil solid phase, which is volumetric heat capacity of the soil solids. The second and third terms are heat storage in the water vapor and liquid water, respectively. The latent heat of vaporization is in the fourth term. The fifth term includes heat involved with differential wetting. The negative sign on the differential wetting implies that an increase of soil moisture content would reduce heat storage.

Inserting Eq. (12) into the left side term of Eq. (11) gives (heat storage varied with time),

$$\begin{aligned} \frac{\partial S_h}{\partial t} = & \left\{ (T - T_o)(c_L \rho_L - c_v \rho_v) - L_o \rho_v - \rho_L W + \theta_a[(T - T_o)c_v + L_o] \frac{\partial \rho_v}{\partial \Psi_m} \frac{\partial \Psi_m}{\partial \theta_L} \right\} \frac{\partial \theta_L}{\partial t} \\ & + \left\{ C_d + c_v \rho_v \theta_a + c_L \rho_L \theta_L + \theta_a[(T - T_o)c_v + L_o] \frac{\partial \rho_v}{\partial T} \right\} \frac{\partial T}{\partial t} \end{aligned} \quad (13)$$

The spatial heat flux given in the right side of Eq. (11) combined with heat flux over a cross-sectional area as in Eq. (10) is combined to give,

$$-\frac{\partial q_h}{\partial z} = \frac{\partial}{\partial z} \left[(\lambda_* + L_o \rho_L D_{Tv}) \frac{\partial T}{\partial z} + L_o \rho_L D_{mv} \frac{\partial \Psi_m}{\partial z} - (T - T_o)(c_v q_v + c_L q_L) \right] \quad (14)$$

Taking the latent heat of vaporization at reference soil temperature as $L(T) + (c_L - c_v)(T - T_o)$, the terms become,

$$-\frac{\partial q_h}{\partial z} = \frac{\partial}{\partial z} \left[(\lambda_* + L_o \rho_L D_{Tv}) \frac{\partial T}{\partial z} + \rho_L [L(T) + (c_L - c_v)(T - T_o)] D_{mv} \frac{\partial \Psi_m}{\partial z} - (T - T_o)(c_v q_v + c_L q_L) \right] \quad (15)$$

Placing both Eqs. (13) and (15) into Eq. (11) gives (Heitman et al., 2008a),

$$\begin{aligned} & \left\{ (T - T_o)(c_L \rho_L - c_v \rho_v) - L_o \rho_v - \rho_L W + \theta_a[(T - T_o)c_v + L_o] \frac{\partial \rho_v}{\partial \Psi_m} \frac{\partial \Psi_m}{\partial \theta_L} \right\} \frac{\partial \theta_L}{\partial t} \\ & + \left\{ C_d + c_v \rho_v \theta_a + c_L \rho_L \theta_L + \theta_a[(T - T_o)c_v + L_o] \frac{\partial \rho_v}{\partial T} \right\} \frac{\partial T}{\partial t} \\ & = \frac{\partial}{\partial z} \left[(\lambda_* + L_o \rho_L D_{Tv}) \frac{\partial T}{\partial z} + \rho_L [L(T) + (c_L - c_v)(T - T_o)] D_{mv} \frac{\partial \Psi_m}{\partial z} - (T - T_o)(c_v q_v + c_L q_L) \right] \end{aligned} \quad (16)$$

The right side of Eq. (16) gives the heat fluxes by conduction, latent heat of vaporization, water vapor sensible heat, and liquid water sensible heat. Heat fluxes by soil temperature gradient and soil matric potential gradient result in time-varied moisture content and temperature in the soil as on the left side of the equation. When modeling soil moisture content and temperature distributions, Eqs. (9) and (16) are solved simultaneously.

Fig. 1 shows the apparent thermal conductivity (λ_{app}) values for selected soils at various moisture content values. The λ_{app} value represents the thermal conductivity as a summation of all transfer mechanisms included in Eq. (10) (Goh and Noborio, 2016). In conditions where liquid and vapor fluxes become insignificant, the equation reduces to the pure thermal conductivity, that is the first term on the right side of Eq. (10), excluding the temperature gradient.

Fig. 1 Apparent soil thermal conductivity with soil moisture content for sandy loam and silty clay soils at 3.5 and 81 °C. Note the effects of both temperature and texture over the range of soil moisture contents. Pore-scale model

A pore-scale model represents phenomena at the pore level, which can be considered microscopic in relative comparison to the continuum approach phenomena at the macroscopic level (i.e., representative elementary volume), for example, Darcy's law. For this reason, a pore-scale model can be viewed as a more fundamental approach than the macroscopic level model. Pore-scale models consist of the volume of fluids method, lattice Boltzmann, stochastic rotation dynamics, pore-network model, level set method, and phase-field. The pore-network model can be used to model water distribution in porous media. The model is represented by random sizes of network pores and throats that correspond to the empty spaces between the particles (e.g., sand particles) and the linkages for mass transfer between the empty spaces. Throats have different widths or radii for cylinder throats.

The Prat (1993) model uses step rules (or algorithms) to guide the mechanisms of standard invasion percolation into an initially saturated two-dimensional porous medium (permeable at the top boundary) by neglecting evaporation. These steps are: (1) at each step, non-wetting fluid invades the widest throat (and adjacent pore) that has the lowest capillary pressure (or suction), (2) regions of isolated wetting fluid, which are isolated clusters of pores and throats filled with wetting fluid, are trapped and cannot be invaded due to wetting fluid incompressibility [where the isolated clusters are parts of the central single wetting fluid cluster before it was separated by invading non-wetting fluid], and (3) the invasion end when the non-wetting fluid reaches a pore at the exit surface at the bottom boundary.

Prat (1993) then introduced a drying algorithm to replace the invasion percolation algorithm. Steps are: (1) identify all clusters in the network, (2) identify the throat with the lowest capillary pressure for each cluster, (3) calculate the evaporation for each boundary cluster, (4) the calculated evaporation flux in step 3 is assigned to the throat in step 2, for each cluster, (5) the throat with the adjacent pore in step 2 is drained, and (6) update the fluid distribution in the network. Including the effect of gravity, the jump potential is estimated for each throat,

$$Q_b(h) = -\frac{2\gamma}{r_b} + (P_g - P_l(h)) = -\frac{2\gamma}{r_b} \left(1 - \frac{\Delta\rho g L r_b}{2\gamma} \frac{(L-h)}{L} \right) = -\frac{2\gamma}{r_b} \left(1 - B \frac{(L-h)}{L} \right) \quad (17)$$

The throat invasion potential is given by the difference between the surface tension resulted pressure ($-2\gamma/r_b$) and gas-liquid hydrostatic pressure ($P_g - P_l(h)$). Equation (17) is used to estimate and identify the throat with the lowest capillary pressure in step 2. Including the effect of viscosity, Darcy's law equation, the Hagen-Poiseuille capillary equation, and the mass balance equation are used (Prat, 2002). Similarly, the equations for water vapor diffusion between pores through the throat, evaporation rate above water meniscus at the adjacent throat, and mass balance in the vapor phase are also reported in Prat (2002). Refer to Nowicki et al. (1992) for further information on these equations. The effects of a temperature gradient on the surface tension gradient and the saturation vapor partial pressure gradient are included. In addition, a more detailed pore-scale approach has been used to study vapor transport in porous medium, for instance, the vapor enhancement mechanism caused by the connected capillary pathways (or the liquid island effect) (Shahraeeni and Or, 2012).

In addition to the investigation of fundamental mechanisms at the microscopic level, parameters at the macroscopic level can be estimated, for example, liquid relative permeability, capillary pressure, fluid effective diffusion, the pressure of capillary (Nowicki et al., 1992), and the effective heat transfer coefficient.

Applications of heat and water movement

The soil moisture and heat transfer equations developed by Philip and de Vries (1957) and de Vries (1958) have been used in several soil studies. The heat and moisture model has been extended to include other mechanisms. For instance, Nassar and Horton (1997) extended the equation to include solute transport mechanisms. Liang et al. (2017) used the soil heat and moisture movement model coupled with crop growth to model the soil moisture content, temperature, leaf area index, dry matter, and crop yield in rice fields. Bai et al. (2020) improved the soil water and heat equations to include soil deformation. Although the advantage of having a fully coupled heat and moisture simulation model is evident, some researchers have also provided meaningful estimates with a simplified decoupled version of the equations. For instance, Ni et al. (2019) decoupled the soil heat and moisture mechanisms into a simplified model for estimating the mass transport using the Richards equation and for estimation of soil temperature using an empirical equation. Heitman et al. (2008b) estimated soil water evaporation with depth and time.

The soil heat and moisture equation have been used to model soil temperature and water content distributions. Modeling of soil heat and moisture has also been possible under slightly more extreme conditions, as noted in the study of Kelleners et al. (2016) on water infiltration of snowmelt. Massman (2015) likewise used soil heat and moisture equations to study high-temperature sand-water-steam systems, for wildfires and prescribed burns.

Moreover, soil heat and moisture modeling has been reported in specific engineering applications. Chalhoub et al. (2017) studied ground heat exchangers using simplified heat and moisture equation corresponding to Fourier's law thermal conductivity driven heat flux and simple water budget equation based on soil water content, rainfall rate, and evaporation rate.

Soil heat and moisture equations have also been applied in studies of specific mechanisms. For example, Vanderborght et al. (2017) summarized the application of heat and water transport to justify the need for a 3-dimensional representation of processes to study vapor transport in soil.

Heat and water transfer continuum model limitations

The heat and water transfer equations have some limitations (Heitman et al., 2008a). The limitations are based on considered, not considered, and yet discovered, understood, or quantified phenomena. First of all, the governing equations described in this review are limited to mass and heat transfer in a vertical direction. When mass and heat transfer take place in two- or three-dimensional spaces, the one-dimensional governing equation should be expanded to account for those dimensions. The mass transport is driven by soil matric potential and temperature gradients and gravitational force, while heat transfer is based on conduction, latent heat convection, and sensible heat convection. The governing equations can be extended to account for solute transport and osmotic effects (Nassar and Horton, 1997). For structured soil, the pore domain could be fractioned into dual-permeability, that is, separate permeability for the soil matrix and the macropores (fractures).

The equation assumes rigid porous media. Under non-rigid media conditions, the effect of bulk density can be included to describe water and temperature distributions (Kojima et al., 2018). Also, hysteresis in water retention curves may or may not be accounted for in the model, depending on the constitutive equation used. Milly (1982) included hysteresis. In addition, local thermodynamic equilibrium and equilibrium liquid-vapor phase usually are assumed. A non-equilibrium liquid-vapor change model has been proposed, but it has limited precise predictions of soil moisture distributions (Massman, 2015).

Furthermore, uncertainty in parameter calibration on unsaturated hydraulic conductivity and vapor flux has been a common concern (Heitman et al., 2008a). Additional uncertainty is encountered when the model soil system is exposed to open air with atmospheric pressure fluctuations due to wind gusts, possibly adding more uncertainty to model predictions (Scanlon and Milly, 1994). Water evaporation from the soil surface and the associated drying front depth (length), which is the result of the force balance between capillarity, gravity, and viscous dissipation (Lehmann et al., 2008), may also affect the application of heat and mass transfer theory.

Mechanisms leading to the excessive vapor fluxes sometimes observed under temperature gradients are also not fully understood (Philip and de Vries, 1957). Cass et al. (1984) quantified the vapor enhancement factor at various temperatures, soil moisture contents and air pressures. Hiraiwa and Kasubuchi (2000) simplified the experimental method by excluding pressure control and simplified the mathematical equation for estimation. Air volume expansion and contraction by diurnal temperature variation has also been investigated in the field (Parlange et al., 1998). A pore-scale model which incorporates the liquid island effect confirms the Philip and de Vries's vapor enhancement postulation at low soil moisture content values (Shahraeeni and Or, 2012). Other than air flux, a liquid to vapor phase change which results in vapor volume expansion advection (inferred from the universal gas law) has also been suggested (Goh and Noborio, 2016). Again, the Lu et al. (2020) measurements identified excessive vapor flux which reaffirms the need for including new mechanisms that could be considered as either air volume expansion advection, vapor volume expansion advection, or a combination of both. Another mechanism, vapor buoyancy, has not been investigated even within pore-scale models (Shahraeeni and Or, 2012).

Additional applications of coupled heat and mass transfer models

Coupled heat and mass transfer models have useful applications to several earth and environmental system topics, including fate and transport of volatile organic materials such as BTEX compounds, pesticides, and greenhouse gases (GHG). Dynamic heat and water transfer connects to soil temperature and water content distributions. Temperature and water content impact microbial activity, which influences chemical sinks and production rates, and they also influence gas diffusion rates. Therefore, coupled heat and water transfer is not only important to estimate dynamic soil temperature and water content as connected to surface heat balance and surface water balance, but the dynamic soil temperature and water content distributions are necessary to estimate organic chemical transport and greenhouse gas fluxes.

Summary

Work to-date reveals the mechanisms driving fluxes of heat and mass in an unsaturated porous medium. The heat and mass transfer equations can be solved simultaneously to describe the temperature and water distributions in soil. Model estimated temperature and moisture distributions in soil have many important applications in agriculture and engineering, and the diversity of applications continues to expand. The model can be used as the basis for expansions to include additional mechanisms such as solute transport, greenhouse gas emission, soil deformation, dual-porosity, and dual-permeability, or for investigations of unclear mechanisms like the vapor enhancement factor. The pore-scale model provides promising opportunities to study heat and mass transfer mechanisms in undisturbed soils, especially the effects of soil particle arrangement and the resulting distributions of pore and throat sizes. However, similar to the macroscopic scale theory, microscopic model mechanisms have to be calibrated and validated.

Abstract

Radiation balance represents the difference between the incoming and reflected solar radiation and the incoming and emitted longwave radiation at the earth's surface. A positive energy balance indicates that the energy impinging on the earth's surface has the capacity to evaporate water, heat the air, heat the ground, or drive photosynthesis while a negative energy balance shows that energy is being lost from the earth back to the atmosphere. It is this balance of energy that determines our ability to sustain life on earth.

Key points

- Radiation balance determines the amount of energy available at the earth's surface to heat the air or ground, evaporate water, or drive the photosynthetic process.
- Radiation balance is comprised of the short-wave (sunlight) and long-wave (derived from temperature of objects) components at the earth's surface.
- Radiation balance varies with time of day, time of year, location on the earth, and surface properties of ground.
- Radiation balance is affected by the climate and affects the climate and understanding these effects will enhance our ability to ensure food supplies, stable ecosystems, and environmental quality.

Radiation balance

Life on Earth depends upon the flow of energy. Living objects balance their energy inputs with outputs to create a comfortable environment. Humans have an advantage because they create clothing and shelter to help modify their environment. Plants and soil also have inputs of energy, but have limited controls on the dissipation of energy and even less control on the energy inputs into the system. When we begin to think about the balance of energy in the soil or plant system, we can begin to understand some of the remarkable balances that exist within the natural environment. Understanding the surface radiation and energy balances provides an opportunity to explore the role of different components (e.g., crop residue, tillage, cover crops), on soils and the environment (Monteith and Unsworth, 2013; Rosenberg et al., 1983).

The balance of radiation is similar to a checkbook or savings account. How much money is in it at any one time depends upon how much has been put into the account and how much has been taken out. This balance can be expressed very simply in word form. Net radiation is the difference between the gains (incoming solar radiation and absorbed long-wave radiation) and losses (reflected and transmitted solar radiation and emitted longwave radiation). This 'budget' can be expressed mathematically as:

$$R_n = (1 - \alpha)S_t + L_d - \varepsilon\sigma T_s^4 \quad (1)$$

where R_n is the net radiation at the surface expressed as the amount of energy (joules) per unit area (meters squared) per unit time (seconds) or watts per meter squared. All of the radiation terms (S_t , L_d , and $\varepsilon\sigma T_s^4$) in Eq. (1) must have the same units to avoid problems. As we expand these terms, S_t is the solar radiation input, α the albedo or reflectance of the surface, L_d the input of longwave radiation, $\varepsilon\sigma T_s^4$ is the energy lost as longwave radiation from the surface. Shortwave radiation represents the energy in the 0.3- to 3- μ m range, while longwave radiation represents wavelengths of more than 3 μ m. Another way to consider this difference is that shortwave radiation originates from the sun, with a surface temperature near 6000 K, while longwave radiation is emitted from objects with temperatures near 300 K. Current technology with radiometers allows for the direct measurement of these components

*Retired

and is shown in Fig. 1 as a 24 h sequence of incoming shortwave, reflected shortwave, incoming longwave, and emitted longwave for 4 days over a maize field in central Iowa. The convention that is used for the radiation balance components is that positive values show energy directed toward the earth's surface and negative energy values are directed toward the atmosphere. In this sequence of days, there are days in which the solar radiation is affected by cloud cover and show a large variation in the values, which affects how much solar radiation is reflected back to the sky. The longwave components do not exhibit a large change when it is cloudy (Fig. 1). Only the longwave components are detectable at night because there is no energy from the sun after sunset and before sunrise (Fig. 1). On a cloudy day, there is a marked reduction in solar radiation and longwave components become nearly equal. The radiation balance for a surface is the combination of these components and are shown for these 4 days in Fig. 2. Radiation balance values throughout the day do not always produce a smooth curve because of the presence of clouds. Nighttime values are zero or below because the Earth's surface tends to lose more energy than it receives. Energy available as net radiation is further divided into other components. We express the energy balance as:

Fig. 1 Components of net radiation for 4 days (DOY 167-170) in June over a maize canopy in central Iowa showing shortwave (SW) and longwave (LW) inputs from the sun (in) and emitted from the back from the land surface (out).

Fig. 2 Net radiation balance for 4 days (DOY 167-170) during the midsummer growing season in central Iowa based on the components shown in Fig. 1.

$$R_n = LE + H + G \quad (2)$$

where LE represents the energy used to evaporate water, H the energy to heat the air, and G the amount stored in the soil volume. The more energy input to the surface the greater the potential magnitude of these components (see section “energy balance”).

Incoming solar radiation

Solar radiation originates at the Sun and travels through space and the Earth’s atmosphere before it reaches the Earth’s surface. Solar radiation consists of two components, the direct component (S_b) and the diffuse (S_d) component. Diffuse radiation comes from all angles, while the direct beam follows the path of the Sun throughout the day. Diffuse radiation is formed by the scattering of the direct beam by particles in the atmosphere. Physically, we can observe the effect of direct and diffuse radiation by sharpness of shadows. On a clear day, the outlines of the shadows are clearly defined, while on a cloudy day there are no shadows yet we still can see. Mathematically, we represent incoming solar radiation as:

$$S_t = S_b \sin \beta + S_d \quad (3)$$

The angle of the Sun’s beam above a horizontal surface, β , distributes the energy in the beam over a different area than if the surface were perpendicular to the beam. The magnitude of direct and diffuse radiation depends upon the solar elevation (the angle of the Sun’s beam above the horizon), the amount of scattering and absorption by atmospheric gases and aerosols, and the amount of scattering and absorption by water droplets and ice particles in the clouds. Particles in the atmosphere have a large impact because they scatter radiation in all directions, some back to space and some toward the Earth’s surface. As the number of particles in the atmosphere increases the portion of diffuse radiation increases.

There is large variation in the incident solar radiation at many locations throughout the year because of the changing angle of inclination of the Earth with respect to the Sun. At the equator there is little difference; however, at the midlatitudes there are large differences between summer and winter. At 42°N latitude, clear-sky solar radiation incident on the Earth at midday is approximately 26 J m⁻² per day during summer, but approximately 9 J m⁻² per day during winter. Clouds affect these totals and need to be considered. There are tables of clear-sky solar radiation incident on the Earth’s surface for any location: these tables have been assembled through measurements and empirical calculations.

The slope of the surface is a critical factor in the radiation balance. If there is a south-facing slope in the northern hemisphere then more energy is going to be absorbed than if there is a north-facing slope. More subtle differences exist if the slope of the soil surface is changed with tillage implements. The creation of a furrow with a tillage tool that runs east to west across the field creates a surface in which one part will receive more direct solar radiation than the other. This will cause the soil surface and soil temperatures to be warmer on the south side and cooler on the north side in the northern hemisphere.

Temperatures for bare soil at the surface under these conditions may be 10–20 °C different at midday. This same furrow shape placed in a north-south direction will have differences in surface temperatures from morning to afternoon. The geometry of the surface plays a critical role in the radiation balance through the effect of direct-beam solar radiation. Manipulation of the soil surface through tillage implements can create a specific microclimate at the soil surface that influences temperature-dependent processes within the soil.

Albedo

Albedo of a surface is the ratio of amount of solar radiation reflected back to the atmosphere to the amount of incoming solar radiation (S_r/S_i). We see a highly reflective surface as white, and a low-reflectance surface as black. A dark surface will absorb more radiation than a light-colored surface. The range of albedo values for different surfaces is shown in Table 1.

Albedo is more complex than assuming a single constant value for an agricultural soil surface. Albedo values for a soil surface change with soil water content, type of soil, tillage practice, amount and type of crop-residue cover, and age of residue. Agricultural soils are modified by tillage, residue placement, and the growth of a crop and throughout the year there is a constant change in the albedo of a soil surface. Starting with a smooth soil surface with an albedo of 0.20, the addition of water to a soil surface decreases the albedo to 0.15, with a slow return to the original value as the surface dries. Water is an effective absorber of short and longwave radiation and adding water decreases the albedo of any surface. If the same surface is roughened by tillage, there is a further decrease in the albedo of a dry surface to near 0.15. This decrease is due to the change in the soil surface that traps more direct- and diffuse-beam solar radiation because of the change from a smooth to a rough surface. Wetting this tilled surface further decreases the albedo. Adding a fresh crop residue increases the albedo because of the highly reflective nature of the crop residue; however, as the residue ages, the albedo decreases and may be only slightly different from the soil surface in the spring. Soil surfaces are continually undergoing changes that affect their albedo. This will impact the radiation balance and ultimately the evaporation of water from the surface, heating the air, and warming the soil.

The albedo values shown in Table 1 represent an integrated value over the shortwave wavelengths and are determined by measured the incoming solar radiation with a pyranometer and reflected radiation with an inverted pyranometer of the same type. Within the solar radiation spectrum, there are differences in reflectance, as shown in Fig. 3 for a corn leaf. There is a dramatic change

Table 1 Albedo values for different natural surfaces.

Surface	Albedo
Bare soil, dry	0.20
Bare soil, wet	0.15
Bare soil, fresh corn residue	0.35
Bare soil, weathered corn residue	0.22
Corn canopy	0.22
Wheat canopy	0.26
Rice canopy	0.24
Deciduous forest with leaves	0.18
Coniferous forest	0.16
Tundra	0.20
Fresh snow	0.80

**Fig. 3** Reflectance spectra for a corn leaf in the visible and near-infrared wavelengths.**Fig. 4** Reflectance of solar radiation across visible and near-infrared wavelengths for a smooth, tilled, Nicollet soil when wet and dry.

in the reflectance between the visible and near-infrared wavelengths from $0.6 \mu\text{m}$ to $0.7 \mu\text{m}$. The difference in reflectance spectra across the wavelengths in plant material shows low reflectance values in the blue and red portions of the spectrum, an increase in the green wavelengths, and then a sharp increase in the near-infrared wavelengths. Reflectance values for a bare soil across the solar radiation wavelengths show a different pattern from a leaf and tend to increase linearly with wavelength, not showing the large differences among portions of the spectrum (Fig. 4). Tilling the soil to change the roughness and increases in soil water content will affect soil reflectance. There is a decrease in the reflectance values for all wavelengths (Fig. 4). Adding crop residue to the soil

surface also changes the reflectance of the surface and changes the energy-balance components. Melting of snow greatly decreases albedo, resulting in soil warming.

When solar radiation impinges on a leaf or any other object, the radiation may be reflected, absorbed, or transmitted. If we imagine ourselves underneath a thin layer of white cloth, from the upper side we would see the white color owing to reflection of all wavelengths; however, underneath the cloth we would still see because of the light being passed through (transmitted). Some of the light would be absorbed by the cloth. Under a 10-cm layer of soil, there would be no transmitted light and there would be no shortwave radiation, therefore no visibility. This same principle applies when layers of material are added to the soil surface. A layer with a high light transmittance allows solar radiation to reach the soil surface and warm the soil, evaporate water, or warm the air next to the soil surface. When a highly reflective and low-transmittance material, such as snow, is placed on the soil surface, there is little change in the temperature of the soil surface with varying solar radiation affecting the radiation balance. Transmittance values for different materials vary widely, as shown in Table 2 for both the shortwave and longwave regions of the spectrum. Transmittance of solar radiation through materials, especially plant material, has a large effect on the radiation balance at the soil surface. Very dense canopies transmit some light through all of the layers of leaves to the soil surface. Humans are able to see in this region; however, a leaf receives little energy. Plants grown under other canopy layers often have very large leaves with less chlorophyll (more yellow) than the same plant grown in full sunlight. The radiation balance of these plants and the soil under dense canopies is much different from the environment without this canopy.

Incoming longwave radiation

All objects with an absolute temperature of more than 0 K emit energy. Objects in our atmosphere such as gases, particles, ice crystals, or water droplets have temperatures above absolute zero and emit energy. The energy emitted is equivalent to the 4th power of their temperature as described by the Stefan-Boltzmann law $E = \epsilon \sigma T^4$. The Stefan-Boltzmann constant, σ , is $5.67 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-1}$. The amount of energy emitted by an object greatly increases as the temperature increases. The emissivity term, ϵ , can be considered an efficiency factor. The higher the emissivity of an object the more effective the emission of longwave radiation away from the object. Longwave radiation is measured with radiometers designed to capture only these wavelengths; however, there are relatively few of those instruments located around the world. Incoming longwave radiation is generally estimated from mathematical equations in which the emissivity of the atmosphere, ϵ_a , is estimated through a combination of water vapor or temperature measurements to modify the energy relationship to $\epsilon_a \sigma T_a^4$. In one of the original relationships for this estimation, it was proposed that $\epsilon_a = 0.51 + 0.66e_0^{1/2}$, where e_0 is the water vapor pressure of the atmosphere. There have been several attempts to refine this relationship, for example, where ϵ_a is estimated by $0.575e_0^{1/7}$ and ϵ_a is best represented by $0.70 + 5.95 \times 10^{-5} e_0 \exp. (1500/T_0)$, with T_0 the air temperature in degrees Kelvin (Hatfield et al., 1983). Both e_0 and T_0 are obtained from meteorological station data at a height of 2 m above the surface and are available every hour throughout the day. A comparison of all of these different methods with data collected across the United States has found that there is little difference among the methods and all predicted longwave radiation to within 5% of the measured values. Emissivity values for clear skies can range from 0.6 to 0.75, and these equations apply to the clear-sky condition. When there are clouds, the ϵ_a term can be considered to be near 1. Consider what happens to air temperature on a clear versus a cloudy night. On the clear night there is a rapid drop in air temperature because the atmosphere is contributing little energy to the Earth's surface. On a cloudy night or an extremely humid night there is little change in air temperature because the longwave radiation lost from the Earth is captured by the clouds or water vapor and reemitted back to Earth's surface.

Terrestrial longwave radiation

Objects on the Earth's surface have a temperature and emit energy in relationship to their temperature as discussed for longwave energy emitted from the atmosphere. The same principle applies to the soil surface or objects on the Earth's surface. The last term in Eq. (1), $\epsilon_a \sigma T_s^4$, represents the loss of energy away from the surface into the atmosphere. Emissivity values for objects on Earth are

Table 2 Transmittance values for different natural surfaces.

Coniferous forest	0.99

close to 1; however, there is variation, as shown in Table 3. The variation is small and often the assumption is that 0.95 or 0.97 are adequate mean values that can be used. The T_s term in the relationship represents the surface temperature of the object. This would be the temperature at the outer surface of an object or at the very top layer of the soil surface. There are large gradients of temperature in the soil, and for a dry soil the surface temperature at midday may exceed 50 °C while at 10 mm below the surface the temperature is less than 40 °C. In the estimation of the longwave energy lost from the surface, a longwave radiometer can be inverted over the surface to measure the amount of energy escaping or estimated using measurements of surface temperature obtained from infrared thermometers combined with an estimate of emissivity for the surface. The latter approach works quite well for smooth or uniform surfaces; however, for rough or undulating surfaces or surfaces comprised of a combination of plants and soil, there is a large variation in surface temperature and measurements would have to be made that would represent the average value for the entire surface area. The magnitude of the energy lost from surfaces with different temperatures is shown by Fig. 5. As the surface temperature increases, the energy emitted increases rapidly, because emission is a function of the 4th power of surface temperature.

Radiation balance

Each of the terms in Eq. (1) has been discussed separately to develop an appreciation for the variation within each component and the factors that affect the magnitude of the energy within each term. As these components are reassembled into the radiation balance for a surface it is possible to see how soil-management factors might affect the radiation balance. There are changes throughout the day as shown in Fig. 2. If the radiation balance is expanded into the components for each hour throughout the day, the differences that each component adds to the balance can be seen. The largest factor is the solar radiation term, and the difference between the 2 days is a direct result of the incoming solar radiation. The least amount of variation among days is introduced by the incoming longwave radiation, L_d , since this factor is primarily affected by air temperature. Longwave loss is actually highest during the day when the surface temperatures are highest. As these relationships are expanded into annual radiation balances, surface temperature and air temperature variations among days across the seasons have a large impact. If the annual radiation balance over the year is computed, the sum of the inputs and losses is nearly zero.

On a daily interval, changing the soil surface through tillage or crop-residue management has a large impact on the radiation balance. If a smooth, dry soil is tilled, there are several changes in the radiation balance components. Incoming solar and longwave radiation do not change. The albedo decreases so there is a greater adsorption of solar radiation leading to a greater amount of energy available at the soil surface. However, evaporation of soil water from the wet, rough surface decreases the surface

**Fig. 5** Energy emitted from a soil surface under different surface temperatures.

temperature, creating a situation in which the surface emits less energy. The end result is a surface that has an increased amount of energy available than did the surface before tillage. This effect lasts only as long as there is soil water to evaporate, but there is some effect of the rough surface on reducing the albedo of a dry soil; however, this effect is small compared with the initial period with a wet soil surface.

The final example is the soil surface to which crop residue has been added. In the case of fresh crop residue there is an increase in the albedo of the surface and a reduction in net radiation. Weathered residue decreases the albedo and allows the surface to have an increased net radiation loading. Wetting and drying of the crop residue has some effect on the radiation balance because of the effect of water on both the albedo and emissivity of the surface. Soil-management practices have a large impact on the radiation balance, so knowledge of which factor is affected by management will help provide an improved understanding of the consequences of management decisions.

Implications

The radiation balance of a surface represents the balance of shortwave gains and losses and longwave gains and losses. The radiation balance changes throughout the day and year owing to incoming solar radiation, which has the largest effect on the radiation balance, followed in importance by the cloud cover. The next major factor is the slope of the surface, which affects the amount of solar radiation absorbed. The slope factor can be both a large-scale (slope of hills and mountains) and microscale factor (creation of furrows and ridges with tillage implements). Humans have a large impact on the radiation balance and can manipulate the energy balance through all of the components in the radiation balance.

The radiation balance determines our ability to effectively produce food required for food security; however, it is not the only factor in the complex set of processes linked in plant growth. Understanding the basic source of energy at the earth's surface provides the context for how ecosystems function and thrive.

Abstract

Pore-scale interactions cause ice in sediments to melt over a range of subzero (centigrade) temperatures; this is a consequence of the phenomenon known as premelting. Liquid potential gradients in ice-infiltrated sediments drive flow from warmer to colder temperatures and from fine-grained to coarse-grained regions, supplying ice growth that can produce frost damage as a result of ice–sediment stresses that strengthen with cooling. On thawing, elevated liquid contents can reduce sediment strength dramatically while drainage is inhibited by residual pore ice. Appreciable enhancements to solute concentration during freezing and dilution during thawing also have important biological and mechanical consequences.

Key points

- surface energy and wetting interactions produce temperature-dependent variations in pore space ice and liquid saturation levels, with notable reductions in permeability under colder ice-clogged conditions
- stresses, transmitted between wetted ice and sediment surfaces, strengthen and promote deformation in colder regions, where ice growth is supplied by residual liquid driven down potential gradients that parallel the conductive heat flux
- liquid supply down large temperature gradients during transient freezing promotes deformation at cold temperatures and thawing reduces sediment strength while drainage is impeded by nearby ice
- freeze–thaw impacts are minimal in temperate climates, increase in severity in colder climates, and diminish in severity within climates that are cold enough for near-surface unfrozen conditions to be rare
- climate change is expected to reduce freeze-thaw damage in some temperate climates that warm enough to reduce the occurrence and severity of freezing; freeze-thaw damage is expected to increase in cold climates that are warming rapidly and experiencing more freeze-thaw cycles

Introduction

Freeze-thaw cycles can have dramatic consequences, including frost damage to infrastructure, heave of the ground surface, and enhanced erosion of water-logged soils. The modest $\sim 10\%$ density contrast between ice and liquid water is incidental to most of this behavior. Instead, in porous materials like soils, the mechanical disruption associated with freeze–thaw cycles can be traced to two primary underlying factors: (1) the intermolecular forces that transmit stresses between ice and sediment surfaces across intervening liquid films that thin to enable higher stress transmission at colder temperatures; and (2) the progressive clogging by ice of potential flow pathways that restricts the mobility of residual water (referred to collectively as premelted liquid), which is contained both in the films and in high-curvature regions where ice–liquid surface energy enables equilibrium coexistence. Transient heat flow during freeze–thaw cycling results in temperature gradients, which produce gradients in ice–sediment stresses (factor 1) that are balanced by liquid pressure gradients to satisfy force equilibrium. These pressure gradients commonly drive liquid flow toward colder subzero (centigrade) temperatures and draw water from liquid-saturated fine-grained aggregates into larger macropores where ice is present. Permeability reductions cause the liquid flux to diminish along increasingly constricted flow paths

(factor 2), with mass balance satisfied by ice deposition. The accommodation of this additional ice often entails significant deformation (tied to factor 1), sometimes unloading sediment particle contacts to produce segregated ice and driving frost damage at a variety of scales. Upon thawing, the liberation of liquid quantities that exceed close-packed pore volumes causes local strength reductions and enhanced erosion, particularly when drainage pathways are restricted by elevated ice concentrations in nearby regions that remain frozen (tied to factor 2).

Dominant controls

From this basic understanding of how freeze-thaw cycles disrupt soil systems, several factors emerge as dominant controls on the severity of consequences in different environments. These can broadly be categorized as pertaining to (i) local time-evolving thermal conditions, (ii) the distribution and supply of moisture, (iii) soil constitutive behavior, and the presence of additional (iv) mechanical and (v) chemical loads. Interrelationships between these factors lead to the rich variety of observed responses to freeze-thaw cycling, rendering the summary here more illustrative than comprehensive.

Thermal conditions

Frost damage tends to be greatest when the temperature at the ground surface cycles between cold and warm conditions, with thermal properties and the frequency of freeze-thaw cycling determining the depth range over which damped thermal signals propagate. The modern understanding for why such temperature cycling produces damage is rooted in the modified phase behavior of ice and liquid water that is associated with their confinement in small (i.e. pore) spaces (e.g. see Fig. 1C).

Thermodynamic arguments first elucidated by Gibbs (1878) enable the absolute temperature $T = T_{eq}$ at an ice-liquid interface with curvature K to be written in terms of its offset from a reference temperature T_0 in response to changes in the local liquid pressure P_l and the force per unit area P_T (referred to in the literature as the disjoining pressure or the thermomolecular pressure) that is exerted on the ice by a foreign substrate, so that

Fig. 1 (A) Schematic diagram of a soil column, with segregated ice lenses in the cold frozen soil near the ground surface and unfrozen soil at the warmer temperatures prevailing at depth. Immediately beneath the lowest ice lens is a frozen fringe in which the pore space is characterized by gradients in the relative proportions of ice and the liquid water, which is drawn up from below to supply lens growth. (B) Photograph of ice-infiltrated sediments with visible segregated ice in an excavation to a depth of several decimeters. Figure components provided by Dani Or. (C) Close-up view of the ice–water configuration in an idealized pore above the freezing front at which ice first appears. Larger residual liquid pockets found near particle contacts are bounded by surfaces with high ice–water interfacial curvature K and joined by thin liquid films that separate ice from particle surfaces while enabling the transmission of significant disjoining pressures P_T .

$$T_{eq} \approx T_0 - \frac{T_0}{\rho_l \mathcal{L}} (P_T + \gamma_{il} \mathcal{K}) - \frac{\rho_l - \rho_i}{\rho_l} \frac{T_0}{\rho_l \mathcal{L}} (P_l - P_0). \quad (1)$$

Here, ρ_i is ice density, ρ_l is liquid density, $\mathcal{L}$ is the latent heat of fusion, γ_{il} is the ice–liquid surface energy, and the reference pressure P_0 is defined so that $T_{eq} = T_0$ when $P_l = P_0$ under the bulk equilibrium conditions that pertain when the compressive normal stress in the ice σ_n is equal to the liquid pressure P_l , or equivalently $\sigma_n - P_l = P_T + \gamma_{il} \mathcal{K} = 0$. The approximation in Eq. (1) holds under typical environmental conditions since deviations from bulk equilibrium tend to be sufficiently small that the finite compressibility of the liquid can be neglected and the ice can also be treated as perfectly rigid; it should be noted that any changes in liquid solute content c will complicate matters by causing commensurate changes to the reference temperature so that $T_0 = T_0(c, P_0)$. For the important limiting case of pure water (i.e. with $c = 0$) and values of P_0 commonly encountered in near-surface environments (i.e. $P_0 \approx 10^5 - 10^6$ Pa), the ratio $T_0/\rho_l \mathcal{L}$ is approximately 9×10^{-7} K Pa⁻¹, so that a temperature depression, or undercooling, of $T_0 - T_{eq} = 0.1$ K along a flat ice–liquid interface (i.e. with $\mathcal{K} = 0$) entails a thermomolecular, or disjoining pressure of $P_T \approx 10^5$ Pa in a well-drained system for which P_l is maintained at P_0 . This indicates that along an interface where the normal stress on the ice and the pressure in adjacent liquid differ, even a modest undercooling can lead to stress transmission between the ice and pore walls that is large enough to support an appreciable load and often induce significant compaction. Moreover, since the density ratio that multiplies the final term $(\rho_l - \rho_i)/\rho_l \approx 0.08$ is much less than unity, changes in the local temperature tend to be accommodated primarily by changes in P_T and $\mathcal{K}$ rather than by changes in the liquid pressure on its own, leading to significant stress gradients even when liquid transport is restricted so that P_l deviates from P_0 .

As described by Eq. (1), the strength of the net force per unit area P_T (i.e. factor 1 discussed in the “Introduction” Section) exerted between ice and soil particles (or other foreign substrates such as rock, pipes or concrete) across intervening premelted liquid films increases at colder temperatures that are offset further below bulk melting – that is 0 °C at atmospheric pressure for pure water and the liquidus temperature when solutes are present (e.g. Dash et al., 2006). In addition to the local temperature, the temperature gradient is important as well, both because of its influence on the potential gradients that drive liquid supply through a process that is often referred to as cryosuction, and because of its connection to changes in relative permeability that restrict liquid transport (i.e. factor 2 discussed in the “Introduction” Section) (e.g. O’Neill and Miller, 1985; Rempel et al., 2016; Walder and Hallet, 1986). A predictive understanding of the effects of freeze–thaw cycling is hence intimately tied to assessments of how the local temperature in ice-bound porous media varies through time and space (e.g. a common wintertime spatial pattern is illustrated in Fig. 1A).

Because the depth range over which significant temperature changes occur near the ground surface is typically much shallower than the horizontal length scales upon which variations of similar magnitude take place, thermal conditions in the subsurface are often approximated well by idealized one dimensional energy balance considerations. The time t and depth z varying conductive heat flux perpendicular to the ground surface can be written in terms of the effective thermal conductivity K_e as

$$Q(z, t) = -K_e \frac{\partial T}{\partial z}. \quad (2)$$

Crucially, the surface heat flux $Q_s = Q(z = 0, t)$ that drives temperature changes below is sensitive not only to local meteorological conditions, but also to the insulating effects of snow-cover and crop residues, variations in radiative exchange that are associated with differing slope aspect, albedo, and canopy cover, and factors controlling convective heat exchange, such as surface roughness and the presence or absence of windbreaks (e.g. Sharratt, 1993; Sharratt et al., 1998; Henry, 2007; Santamouris et al., 1999). Beneath the surface, heat is transported primarily by conduction, with advective contributions from heat carried by moving water or air, typically (though not always) negligible, but in a narrow range of temperatures slightly colder than T_0 (controlled by the soil “Constitutive behavior” discussed below) the latent heat associated with changes in ice content can significantly affect the thermal profile (for example in Fig. 1A such conditions prevail in the labeled frozen fringe).

Setting $T = T_{eq}$ and differentiating Eq. (1) with respect to depth, while making a substitution to express the middle term as proportional to the difference between the normal compressive stress on the ice σ_n and the liquid pressure P_l yields the liquid potential gradient as

$$\frac{\partial P_l}{\partial z} - \rho_l g_z \approx \frac{\rho_l \mathcal{L}}{T_0} \frac{\partial T}{\partial z} + \frac{\rho_l}{\rho_i} \left(\frac{\partial \sigma_n}{\partial z} - \rho_i g_z \right) \quad (3)$$

where T_0 has been treated as constant (valid when solute concentration is uniform, e.g. $c = 0$), and g_z is the component of gravitational acceleration perpendicular to the ground surface. In the idealized case where the stress state in the ice can be approximated as isotropic with a depth dependence that is hydrostatic (i.e. $\partial \sigma_n / \partial z = \rho_i g_z$), the term in parentheses on the right disappears to reveal a simple direct relationship between temperature gradients (or the conductive heat flux represented by Eq. 2) and liquid potential gradients. Since water flow is driven by liquid potential gradients, enhanced water transport is favored when the conductive heat flux Q is high, but the “Constitutive behavior” discussed below entails large reductions in permeability at colder temperatures that impede water transport. As a result, at small sub-zero temperatures, water transport is only modestly restrained, while the capacity for deformation is limited by relatively weak stress transmission between ice and sediment surfaces (i.e. P_T is small). At cold temperatures, large stresses are generated between ice and sediment surfaces, but deformation rates are limited by the restrictions in water supply that accompany the formation of ice lenses and the clogging of pores with high concentrations of ice. As temperatures change through time, these competing factors enable deformation to be most rapid when local conditions are cold enough for ice–sediment stresses to support external loads, yet warm enough for liquid flow to supply ice growth, with thermal

gradients sufficiently steep, both to promote the potential gradients that drive liquid transport and to conduct away latent heat (e.g. Rempel et al., 2016). Freeze–thaw cycling is particularly effective at providing the thermal conditions needed to drive the ice accumulation in sediments that produces frost damage.

Liquid supply

Mechanical disruption from freeze–thaw cycling is most intense when the pore space is completely saturated with ice and liquid water so that gradients in liquid flux can be accommodated only by ice deposition that drives associated deformation, rather than simply by compressing or displacing pockets of residual air and water vapor (e.g. Walder and Hallet, 1986). Substituting the liquid potential gradient from Eq. (3) into the idealized one-dimensional version of Darcy’s law, the discharge velocity q_z of the residual liquid in ice-infiltrated soils becomes

$$q_z \approx -\frac{k}{\mu} \left(\frac{\rho_l \mathcal{L}}{T_0} \frac{\partial T}{\partial z} + \frac{\rho_l}{\rho_i} \frac{\partial \sigma_n}{\partial z} - \rho_l g_z \right), \quad (4)$$

where μ is the liquid viscosity and k is the permeability. (Crucially, k depends on the spatially and temporally varying ice content, as described in the section on “Constitutive behavior”.) The first term in parentheses describes how the liquid water that supplies ice growth is often drawn from warmer temperatures where the liquid potential is elevated relative to colder zones where stronger ice–sediment interactions require that liquid pressures drop to satisfy force balance constraints. To make the connection between liquid transport and heat transport more explicit, the expression for Q from Eq. (2) can be substituted for the temperature gradient to write

$$q_z = \frac{k \rho_l \mathcal{L}}{\mu T_0 K_e} Q - \frac{k}{\mu} \left(\frac{\rho_l}{\rho_i} \frac{\partial \sigma_n}{\partial z} - \rho_l g_z \right), \quad (5)$$

which highlights the fact that in the many common situations for which the first term on the right dominates (i.e. when $\partial \sigma_n / \partial z \approx \rho_l g_z$), the discharge velocity is directly proportional to the conductive heat flux; this motivates the popular term for liquid flow in ice-infiltrated sediments: cryosuction.

Consider, for example, the thermal scenario illustrated schematically in Fig. 1A. When temperature increases monotonically with depth, the lower reaches of partially frozen sediments are supplied by liquid drawn from warmer unfrozen zones below. Here, the liquid flux is directly tied to the (negative, or upwards directed) conductive heat flux through Eq. (5), while the liquid pressure in the unfrozen zone is typically determined by regional groundwater flow considerations. In contrast, during the warm phases of freeze–thaw cycling, the temperature profile is more complicated, with elevated temperatures near the surface giving way to freezing conditions at depth (i.e. Q is positive near the ground surface), typically reaching a minimum (where $Q = 0$) before warming as the depth increases further still (i.e. Q is negative at depth). Such a thermal profile enables continued ice accumulation and associated deformation in the portion of the sediments that overlies colder, ice-clogged layers, as liquid is induced to flow down from above. A special case of this behavior that is perhaps more intuitive, occurs following periods of near-surface thaw in which the moisture that is liberated by melting elevates the water table, helping to cause liquid to seep downwards and refreeze to increase ice concentrations at greater depths.

The situation is more complicated when heterogeneities in the distribution of pore sizes are significant. For example, in temperature regimes that allow fine-grained aggregates to remain fully saturated with liquid water while adjacent macropores contain ice (see “Constitutive behavior” Section), liquid can be drawn out to freeze and drive aggregate compaction, leading to appreciable disruption of soil structure. More generally, however, even such small-scale persistent liquid reservoirs are not required for gradual ice redistribution, as depressed liquid pressures in cold regions can pull in moisture from warmer regions, supplied by partial melting in ice-bound sediments or surface snow. Indeed, even when temperature gradients are completely absent, the difference between the final two terms in the parentheses of Eqs. (4) and (5) describes the potential available to drive liquid transport whenever gradients in the normal stress exerted on the ice surface deviate from hydrostatic so that $\partial \sigma_n / \partial z \neq \rho_l g_z$.

Constitutive behavior

Along a contorted ice–liquid interface within the sediment pore space (e.g. see Fig. 1C), Eq. (1) describes how phase equilibrium is perturbed by the influence of surface energy wherever the interfacial curvature $\mathcal{K}$ is nonzero and by the net disjoining pressure P_T that results from intermolecular forces involving both condensed water phases (i.e. liquid and ice) as well as the molecules of the pore walls (e.g. Dash et al., 2006). The extension of ice–liquid equilibrium from a single bulk melting temperature (i.e. 0°C at atmospheric pressure for pure water) to a lower temperature range results from increasing differences between the ice normal stress and liquid pressure as the temperature drops; this general feature of equilibrium solid–liquid phase behavior, known as premelting, is observed and expected for many different materials besides water. Importantly, the combined effects of $P_T + \gamma_{il}\mathcal{K}$ can be equated with the difference between the compressive ice normal stress and the liquid pressure $\sigma_n - P_l$ irrespective of the detailed nature of the microphysical interactions that generate P_T . However, at a given value of P_T the thickness d of the liquid film that separates the ice

from sediment particles or other foreign substrates depends on how this net repulsive force per unit area is generated. Commonly, in the limit that $\mathcal{K} \rightarrow 0$, $P_T(d)$ is approximated using a power law relationship between thickness d and undercooling $T_0 - T_{eq}$; a logarithmic dependence can be more appropriate when the ice and substrate have a finite surface charge (e.g. Hansen-Goos and Wettlaufer, 2010), but at moderate pH values (i.e. 6–9) predictions suggest that charge densities on ice surfaces are sufficiently weak that this logarithmic regime may be of limited relevance (Daigle, 2021). A rich variety of other possibilities besides simple power-law and logarithmic dependencies exist, all of which share the general feature that thinner films enable stronger net interaction strengths so that $\partial P_T / \partial d < 0$.

The soil freezing curve that describes how the volume fraction of ice within the pore space S_i increases as the liquid water content is diminished at colder temperatures is important for altering the conductive heat flux as a result of latent heat effects and for modulating liquid transport through its influence on permeability variations. Soil freezing curves can be approximated numerically with reference to detailed pore-scale geometrical considerations and film wetting behavior, and measured empirically with a range of techniques, including nuclear magnetic resonance, time domain reflectometry, and calorimetry (e.g. Chen et al., 2020; Hansen-Goos and Wettlaufer, 2010; Watanabe and Wake, 2009). Representative experimental data for the liquid saturation ($1 - S_i$) as a function of the depression beneath the bulk melting temperature, or undercooling ($T_0 - T_{eq}$), is shown for several sediments in Fig. 2A (taken from Horiguchi and Miller, 1983; Watanabe and Osada, 2016). In mathematical models that describe freeze–thaw processes, the change in liquid saturation with undercooling is often approximated by a simple power law (i.e. a straight line on a log–log plot), though it should be recognized that such parameterizations fit the data well over a limited saturation range and can deviate considerably from measured values both at higher and lower saturation levels. Moreover, differences in the pore-scale partitioning between ice and liquid at the same undercooling depending on whether the sample

Fig. 2 Constitutive data for different sediments saturated with a mixture of liquid water and ice. (A) Measured unfrozen liquid saturation as a function of undercooling $T_0 - T_{eq}$. (B) Relative permeability as a function of liquid saturation. Data for sieved Manchester Silt (4–8 μm) and Chena Silt taken from Horiguchi and Miller (1983), data for Tottori Dune Sand, Iwate Andisol, and Fujimori Silt Loam taken from Watanabe and Osada (2016, all measurements shown here were made at the same Darcy velocity of 0.53 m/day). In (A) closed symbols were measured along a melting pathway, whereas open symbols for the Manchester Silt and Chena Silt represent measurements made as the temperature was reduced, showing considerable hysteresis. In (B) all measurements were taken along a melting pathway.

achieved that thermal state during warming (thawing) or during cooling (freezing) can produce considerable hysteresis in measured saturation levels, as shown for Manchester Silt and Chena Silt in Fig. 2A (Horiguchi and Miller, 1983). Because solid ice cannot normally be superheated whereas liquid water is readily supercooled, measurements made along a warming pathway are expected to better represent a sequence of equilibrium states.

Liquid water tends to preferentially wet both ice surfaces and pore walls, causing the micro-scale liquid configuration to resemble that which characterizes vapor–liquid equilibrium in the vadose zone (see Fig. 1C). At warmer sub-zero temperatures, the first ice crystals to reach equilibrium with liquid water occupy the centers of the largest pores (illustrated by the dashed circle in Fig. 1C), which enable the lowest possible values of interfacial curvature $\mathcal{K}$. For example, when the characteristic radius of the largest pores is r_p , recognizing that $\mathcal{K} \approx 2/r_p$ for the largest spherical ice crystals that fit in the pore space, Eq. (1) indicates that these crystals first reach equilibrium at temperature $T_f \approx T_0 [1 - 2\gamma_{il}/(\rho_i \mathcal{L} r_p)]$, which is approximately -0.005°C when $r_p = 10^{-5}$ m and -0.05°C when $r_p = 10^{-6}$ m. The implication is that fine-grained sediments can remain fully liquid-saturated at temperatures that are cold enough for ice to be in equilibrium with residual liquid in coarse-grained sediments. For example, when a soil structure is characterized by larger macropores that separate fine-grained aggregates, residual liquid can remain within the micron-scale pores of the aggregates long after the liquid content of the macropores has frozen almost entirely. Cooling further facilitates the progressive invasion of ice into smaller pores and the ice–liquid interface is distorted into the crevices between adjacent sediment grains (i.e. the larger liquid pockets in Fig. 1C), with the surface-energy penalty associated with increased interfacial curvature compensated by the free energy reduction that accompanies crystallization of residual liquid. The liquid films, which coat pore walls, thin as temperature is reduced, enabling P_T to increase, yet the liquid stores in high-curvature regions diminishes more quickly so that the residual fraction of liquid held in films dominates volumetrically at very cold temperatures. At warmer sub-zero temperatures, curvature effects exert the dominant control on residual liquid volume, enabling the liquid saturation to be determined with reasonable accuracy from the pore geometry and surface curvature considerations alone, without precise knowledge of the functional dependence of $P_T(d)$ (e.g. Chen et al., 2020). It is in this curvature-dominated regime that changes in ice saturation with temperature are most dramatic, enabling latent heat effects to have their greatest contributions to the local energy balance and causing temperature gradients to be diminished. Broadly speaking, sediments that are less well sorted are characterized by a correspondingly larger range of pore sizes that enables the liquid saturation to change more gradually with temperature than in more well-sorted sediments. Interestingly, although the change in liquid saturation level with undercooling in ice-infiltrated sediments is broadly comparable to the change in liquid saturation level with matric potential for the same soil placed within the vadose zone, several studies have highlighted important quantitative differences between freezing–thawing curves and drying–wetting curves that are not fully understood, but may be at least partially sourced to differing degrees of fine-scale particle rearrangements (e.g. Watanabe and Osada, 2016; Ren and Vanapalli, 2019).

The geometrical controls on the temperature-dependent ice saturation $S_i(T_0 - T_{eq})$ also govern changes in the flow paths that determine how the permeability k decreases with increased ice content. It is technically challenging to measure permeability changes with ice saturation, but several reliable datasets have been reported (e.g. Horiguchi and Miller, 1983; Watanabe and Osada, 2016), and successful strategies have been developed to enable numerical predictions for k , particularly in the regime for which S_i is dominated by curvature effects (e.g. Watanabe and Flury, 2008; Chen et al., 2021). Fig. 2B shows measurements of the relative permeability scaled by its liquid-saturated value as a function of liquid saturation level in the same five sediments represented in Fig. 2A. The relationship between relative permeability and liquid saturation is often approximated by a power-law in mathematical models of freeze–thaw processes. Potential liquid transport pathways with the largest cross-sectional areas tend to become ice-clogged first, when the liquid saturation level is still relatively high; because these broader flow paths represent the lowest resistance to water transport under liquid-saturated conditions, their blockage by ice can cause the relative permeability to decrease dramatically with small changes in the liquid saturation level. Considering how changes take place with temperature, significant ice volume fractions can develop and impede residual liquid transport through the pore space of coarse-grained sediments under warmer conditions with S_i increasing dramatically over narrower temperature ranges than in fine-grained sediments. However, despite the relative abundance of liquid water at cold temperatures in the most fine-grained, clay-rich sediments, their low saturated permeabilities limit water transport and hence the ability of freeze–thaw cycles to affect change. As noted above, the dramatic heterogeneities in pore size that often characterize healthy soil structure, for example with clay and organic-rich aggregates separated by macropores, can lead to the development of isolated fine-grained, liquid-saturated pockets embedded in a frozen ice matrix that effectively prohibits the large-scale material transport that is enhanced in these structures under unfrozen or partially vapor-saturated conditions. Local transport from fine grained regions toward macropores can nevertheless take place, accompanied by compaction in regions from which liquid is withdrawn and by the expansion and fracture propagation elsewhere that is needed to accommodate ice growth.

External loads

Net ice–sediment thermomolecular pressures P_T increase by approximately $1.1 \text{ MPa } ^\circ\text{C}^{-1}$ as the temperature is depressed below the normal bulk melting point (i.e. 0°C when effects of solutes are negligible, colder and concentration dependent when they are not). Roads, pipelines, buildings and other common infrastructure elements can be considered as external loads that must be supported by a combination of liquid pressures and sediment-contact stresses under unfrozen conditions, whereas thermomolecular pressures contribute as well when ice is present in the pore space. Segregated ice growth in through-going lenses that span many pore

dimensions (shown in Fig. 1A and B) is particularly important for unloading sediment contacts, requiring that thermomolecular pressures be sufficient to both balance external loads entirely and to support the reduced liquid potentials that are needed to draw additional supply. Mathematical descriptions of segregated ice development invoke two viable mechanisms, either with the gradual unloading of sediment contacts progressing as a consequence of load transfer via connected pore-spanning ice surfaces in zones referred to as frozen fringes (e.g. O'Neill and Miller, 1985; Rempel et al., 2004), or through ice-supported fracture propagation processes emanating from anomalously large pores in heterogeneous media (e.g. Style et al., 2011). When external loads are distributed unevenly, ice accumulation can be mechanically inhibited where larger stresses must be generated to produce displacement, favoring ice growth instead in locations where volumes are expanded more easily. Stones, fence posts, and other objects that penetrate conditions spanning from frozen to thawed are subject to more rapid temperature changes than can take place in adjacent water-logged soils from which latent heat must be removed as ice forms. This can distort isotherms, thereby affecting the timing, rates and consequences of ice growth and sometimes enabling frost action to produce self-organized patterns (e.g. Kessler and Werner, 2003; Peterson and Krantz, 2003).

Solutes

The colligative effects of solutes depress the local melting temperature, enabling liquid to persist to colder temperatures and suppressing ice growth. Effectively, this can be framed as making the reference temperature T_0 in Eq. (1) a function of the solute concentration c . When ice does form, solute molecules are rejected, enhancing their concentration in the residual liquid. Sediment surface chemistry can be affected, causing changes in cohesion and also altering the temperature dependence of melt film thickness. Even starting from relatively dilute liquid solutions in unfrozen conditions, the dramatic reductions in liquid volume during freezing can concentrate solutes enough to affect microbial ecology and cause damage to plants (e.g. Henry, 2007). Thawing liberates abundant quantities of fresh water that cause dilution with appreciable consequences as well.

Climatic dependence of freeze–thaw behavior

Fig. 3 shows the average annual number of days with freezing conditions at the ground surface (Kim et al., 2017). The impacts of freeze–thaw cycles depend on the severity, frequency and duration of freezing conditions. In many temperate regions, for example, winter ground surface temperatures are often frozen at night and thawed during the subsequent day, so that many tens of freeze–thaw cycles accumulate each year (i.e. most of the red and some of the orange regions in Fig. 3). Under favorable conditions, where near-surface water contents are high and soils are sufficiently fine-grained for curvature effects to prevent immediate pore ice formation, yet sufficiently coarse-grained to facilitate permeable liquid transport or situated on hillslopes that act as seepage faces, high night-time heat fluxes that are often dominated by radiation to clear and cold night skies support the growth of needle ice at the ground surface (also known as pipkrake, and as frost flowers or false fungus when hosted on dead wood), while the associated latent heat release prevents freezing conditions from penetrating any deeper. The diurnal needle-ice cycle can loosen a thin veneer of surficial sediments, in part aided by the temporary concentration of excess liquid that is liberated during daily thaw periods, but no substantial external loads can be displaced. In more coarse-grained, or less fully saturated soils under the same environmental

Fig. 3 Average annual number of days with freezing conditions at the ground surface. Note that this map includes glaciated regions, some of which are unfrozen at their beds. Data obtained using satellite microwave brightness temperatures over the period from 1979 to 2014 by Kim et al. (2017).

forcing, frozen conditions can penetrate more deeply (i.e. several centimeters), allowing ice to effectively bind particles together and increase cohesive strength, but the effects are ephemeral and rarely involve substantial water redistribution.

More dramatic freeze–thaw impacts take place when daily mean temperatures are sufficiently low for frozen conditions to penetrate further (i.e. decimeters, as shown in Fig. 1B) below the ground surface and be maintained for several days, weeks, or months (i.e. most of the orange and yellow and some of the lighter green regions in Fig. 3). Diurnal cycles of warmer and colder surface temperatures, notably once again modulated strongly by site-specific radiative forcing, as well as factors affecting convective heat transfer (i.e. wind) and the presence or absence of insulating materials (i.e. snow), can produce oscillations in the heat flux direction and thereby drive liquid transport cycles that supply segregated ice growth, with the potential for significant disruption to infrastructure (e.g. frost heave, frost cracking) and modification of soil structure. This can include both expansion and partial rejuvenation of compacted soils by ice-induced fracture processes, and compaction of fine-grained aggregates as a result of water transport toward ice-bound macropores. The largest ice concentrations are supplied by the most active liquid transport, occurring where temperatures are just sufficiently cold for thermomolecular pressures to support external loads and displace pore walls to accommodate segregated ice growth, while remaining sufficiently warm that the relative permeability is not too reduced, with steeper temperature gradients that accompany diurnal temperature swings of higher amplitude favoring more rapid liquid supply both by generating higher liquid potential gradients and by reducing transport distances from unfrozen liquid reservoirs. With spring thaw, or the onset of “mud season”, previously ice-bound soils lose their integrity while underlying drainage pathways remain frozen and effectively impermeable, often causing further infrastructure damage (e.g. potholes, pipe failure) and soil structure modification (e.g. Ferrick and Gatto, 2005).

In colder climates still, with extended winter conditions that keep surface temperatures depressed well below 0 °C, frozen conditions prevail through most of the year and freeze–thaw cycles can be greatly diminished both in number and effect (i.e. most of the green and some blue regions in Fig. 3). Changes in the direction of heat flow that are driven by surface warming and cooling do produce gradients in liquid potential that enable small changes in ice distribution, but dramatic reductions in relative permeability at cold ambient temperatures limit their magnitude so that winter disruption to infrastructure is often minor and the most notable mechanical effect is the dramatic increase to near-surface cohesive strength (e.g. Qi et al., 2006). Strong, dry winds over cold, bare soils comprised of frozen aggregates and air-filled macropores can encourage significant vapor transport that lowers total near-surface water content. Under the warmer conditions encountered during shoulder seasons, freeze–thaw cycles accumulate and are often accompanied by active near-surface segregated ice growth with attendant deformation and structure modification. Persistent positive surface temperatures that melt near-surface ice accumulations over deeply frozen soils can lead to appreciable seasonal surface water-logging that renders formerly sound wintertime travel routes impassable.

Climate change

Climate change is altering freeze–thaw patterns, producing enhanced effects in some locations while diminishing effects in others. In many cases, ongoing changes to seasonal temperatures may have a relatively straightforward impact on freeze–thaw cycles, typically causing them to decrease in number (e.g. in parts of North America by as many as one cycle fewer per year on average over each of the past 40 years, Kim et al., 2017, see Fig. 4) and often reducing the maximum depth of frost penetration. As a result, some regions with milder climates are becoming entirely frost-free, regions with more severe climates are experiencing less disruption associated with freeze–thaw behavior, and the most frigid locations, many of which are among the most rapidly warming places on Earth, are becoming less deeply frozen and as a result may become subject to enhanced freeze–thaw effects. Simple projections based solely on changes in mean temperature are clearly inadequate, however, as they miss potential local impacts of climate-driven changes in (i) seasonally dependent amplitudes of diurnal surface temperature forcing, (ii) the quantity, seasonality and phase (i.e. snow vs. rain) of precipitation, (iii) the persistence and timing of cloud cover and its effects on radiative forcing, (iv) the type, development, and density of vegetation, (v) the dynamics of microbial communities and nutrient cycling, and (vi) land use and infrastructure development. Modifications to these and other factors that affect the dominant controls on freeze–thaw behavior can both compound and mitigate the effects of baseline warming.

Mitigation strategies

Common strategies aimed at decreasing the damaging effects of freeze–thaw cycles most often take aim at the thermal and hydrological controls, and also sometimes involve more dramatic interventions such as the replacement of fine-grained soils with coarser, less frost-susceptible alternatives. Encouraging insulation by measures (e.g. involving crop residue management) that result in thicker snow-cover can be effective at dampening surface temperature variations and so limiting the potential gradients that drive liquid transport, but snow also provides an abundant water source that can be mobilized to supply segregated ice growth that restricts spring drainage and exacerbates soil erosion. Infrastructure investments can be protected by measures to reduce near-surface moisture content and also to encourage in situ pore freezing, as is more common in coarser materials, rather than segregated ice growth habits. The simple strategy of extending excavations below the frost penetration depth is extremely effective for protecting structures in moderately cold climates, whereas employing refrigeration or elevating structures on pilings to protect infrastructure by ensuring that frozen ground doesn’t thaw can be successful strategies in more severe environments. Tillage practices

Fig. 4 Change in the annual number of frozen days in North America over the 40-year period from 1979 to 2019. Dark gray areas represent permanently frozen surfaces like glaciers and land that freezes only very rarely. Data derives from a 2020 update by Kim and Kimball from data originally published by Kim et al. (2017), made available by the United States Environmental Protection Agency as one of the Climate Change Indicators at epa.gov/climate-indicators.

that loosen and rejuvenate soil structure can also enhance fall drainage and lower the effective thermal conductivity further by mixing in crop residues so that frost penetration depths are reduced, which can be particularly effective at limiting freeze–thaw disturbance when subzero temperatures are encountered only above the water table. Where snow cover is minimal, the influence of albedo on radiative heat transfer can be employed to encourage earlier spring thaw by darkening the ground surface, for example with autumn residue burning.

Outlook

The basic processes involved in freeze–thaw cycling are well-understood, yet their combinations and interactions can be complex and remain challenging to describe in predictive quantitative simulations. Uncertainties in soil constitutive behavior are confounded by heterogeneity, with constraints generally much better for soil freezing curves than for relative permeability treatments, which are inherently much more difficult to validate. The evolution of geotechnical properties and soil structure with repeated freeze–thaw cycling requires further study. Most model treatments of freeze–thaw behavior are idealized to consider fully water and ice saturated porous media, despite the importance and ubiquity of partial air-saturation, particularly in agricultural applications. Efforts that account for solute redistribution, including the effects of changing pore-water composition on soil freezing curves and relative permeability functions, are also poorly represented in the literature. Despite considerable progress in unravelling the mechanics of segregated ice growth, the relative importance of ice-lens nucleation by sediment unloading across discrete temperature horizons in comparison with ice-lens growth by fracture propagation initiated within anomalously large pores remains unresolved. Further attention is also needed to formulate predictive descriptions of gradual ice redistribution within fully ice-bound soils, and to account for poroelastic effects, particularly in regard to the modification of soil structure. Concern over the effects of global climate change and the need to protect infrastructure investments have motivated renewed interest in these and related topics, some of which will undoubtedly be addressed more comprehensively in the coming years.

Abstract

Permafrost is the term used to describe ground (soil or rock) that remains at or below 0 °C throughout the year for at least two consecutive years. In this chapter, we focus on distribution and physical characteristics of Arctic terrestrial permafrost. We discuss the constituents of permafrost (minerals, organic matter, water, ice, and gas) as well as the presence and importance of ice, leading to patterned ground formation. We explain cryo-pedogenetic processes, hydrology, energy, and water balances, snow-vegetation feedbacks, and gas transport in permafrost regions. Finally, we discuss permafrost degradation and its effects on the energy, water, and carbon balances of the Arctic.

Key Points

- Permafrost is spatially distributed across the globe and exerts important controls on land surface energy, water, and carbon balances and the global climate system.
- Permafrost underlies 11% of the total surface of the Earth's exposed land surface.
- Permafrost strongly affects soil genesis due to a unique set of cryo-pedogenetic processes.
- The hydrology of permafrost-affected soils is complex due to seasonal freezing and thawing of the active layer.
- Snow cover and vegetation exert important controls on energy and water balances of permafrost-affected soils and fluxes.
- Thawing of ground-ice-rich permafrost leads to subsidence, with often irreversible changes of landscape topography, hydrology, and carbon cycling.
- The warming Arctic climate is expected to increase the production and release of CO₂ and CH₄ in permafrost-affected soils.

Introduction

Permafrost is an important component of the Earth's cryosphere. It plays a key role in the global carbon cycle, as well as in the ecosystems and infrastructure in Arctic and sub-Arctic climate zones. Permafrost-affected soils have unique energy, water, and carbon dynamics due to periodic freeze-thaw cycles and the underlying continuously frozen ground. Borehole measurements show that Arctic permafrost has been warming during the early 21st century (Biskaborn et al., 2019). Earth system model simulations demonstrate that the carbon release from degrading permafrost due to climate warming represents an important global feedback on climate change, which affects the plausibility of achieving the temperature targets of the United Nations Framework Convention on Climate Change (de Vrese and Brovkin, 2021).

By definition, permafrost encompasses ground (soil, sediments, rocks) that remains at or below 0 °C for at least two consecutive years (French, 2017; van Everdingen, 2005). The permafrost table is the upper boundary of the permafrost, and the ground above the permafrost table is called the suprapermafrost layer. Permafrost layers may be just meters deep in the southernmost permafrost zones, or it may be more than a kilometer deep further north. Permafrost can contain layers of solid ice throughout, which can be up

to several meters thick. The deepest permafrost is located in northern Yakutia where it reaches 1500 m (Melnikov, 1966). Deeper down in the soil is a perennially unfrozen layer where the geothermal heat flux prevents temperatures from falling below the freezing point.

We focus on processes of Arctic terrestrial permafrost, thus excluding formerly terrestrial, now flooded permafrost (submarine permafrost) which underlies large proportions of the Arctic shelf areas. We define “Arctic” to be the region of the common base map provided by the definition of vegetation and associated characteristics (Circumpolar Arctic Vegetation Map, CAVM Team, 2003).

Permafrost layers may not actually be frozen (part or all of the pore water turned into ice), because the freezing point of included water can be depressed several degrees below 0 °C. Water, in either liquid or solid phase, may or may not be present in permafrost. To differentiate between the temperature and water phase of permafrost, the terms “cryotic”/“non-cryotic” and “frozen”/“unfrozen” have been proposed. The former terms refer solely to the temperature of the material, whereas the latter terms refer to the presence of ice in the ground (van Everdingen, 2005; French, 2017). Therefore, perennially cryotic ground is synonymous with permafrost, and permafrost may be “unfrozen,” “partially frozen” or “frozen,” depending upon the state of the ice and water content. The active layer is seasonally frozen; the top layer of the ground freezes in the winter and thaws during the summer. Permafrost-affected soils are closely related to the active layer and upper sections of permafrost.

The thermal and hydraulic dynamics of permafrost-affected soils control the fluxes of energy, water, and carbon between the land surface and the atmosphere. This is of particular interest with regards to current climate warming, which is already pronounced in the Arctic and is anticipated to increase dramatically in the coming decades (Meredith et al., 2019). The warming of the climate leads to degradation of the permafrost and its landforms (Karjalainen et al., 2020), thereby mobilizing large quantities of organic carbon in thawing permafrost soils (Nitzbon et al., 2020). Decomposition and mineralization of organic carbon are expected to contribute to a further increase of atmospheric CO₂ concentration, fueling a positive feedback mechanism to the Earth’s climate (Previdi et al., 2021). Depending on the development of Arctic hydrology, increases in methane production and emission from degraded, wet Arctic soils can lead to additional increases of atmospheric radiative forcing. Permafrost-affected soils can be free of vegetation or covered by treeless tundra vegetation or coniferous taiga forests. While some tree species in the taiga biome can grow on permafrost-affected soils, tree growth is generally prevented by cold summers and short growing seasons in the tundra biome. Changes in vegetation, such as movements of shrub- and tree-lines, affect energy, water, and carbon fluxes and modulate the response to climate change of permafrost-affected soils.

Characteristics of permafrost-affected soils

Distribution of Northern Hemisphere Permafrost

Permafrost underlies an area of $14\text{--}16 \times 10^6 \text{ km}^2$ —around 15% of the exposed Northern Hemisphere or 11% of the total Earth’s exposed land surface (Obu, 2021). Permafrost zones are defined as continuous (90–100% of area), discontinuous (50–90%), sporadic (10–50%), and isolated (10% or less). The mean annual ground temperature (MAGT, °C) at the top of the permafrost is shown in Fig. 1; these model results were validated against ground observations of temperature from borehole measurements (Obu et al., 2019). MAGT ranges from approximately 0 °C to –25 °C in the permafrost. The 0 °C isotherm shows great variation latitudinally, reaching much further south in Siberia compared with North America, for example. Sometimes, permafrost layers are found in areas where they cannot form under present climatic conditions, which reflects past conditions when the climate was colder. These deposits are called “relict permafrost” and are often covered by dozens of meters of unfrozen soil.

Physical characteristics of permafrost-affected soils

The material forming permafrost can be bedrock, sediment, or soil, consisting of mineral and organic solid compounds, ice, liquid water, and gas. Ice existing in the pores of frozen soil is named pore ice. When the absolute ice content exceeds the pore space (porosity) under unfrozen conditions, it is referred to as excess ice. Fig. 2 gives an example of the ice content of a frozen permafrost core section from the Yedoma complex of Pleistocene origin (Lena River Delta, Siberia). The laboratory and computer tomography results show a high ice content, comprising a large volumetric fraction (between 39% and 48%) of excess ice as well as a complex ice distribution (Fig. 2) (Nitzbon et al., 2021, 2022). The ice content and soil texture of permafrost in the Arctic are largely unknown and depend on factors such as history (duration of formation), soil type, soil texture, soil water chemistry, and temperature (Fischer et al., 2020). Thermal and hydrological processes are highly sensitive to the presence of ice and water in the ground. Simulation of permafrost requires implementation of these physical processes, as well as the parameterization of the thermal and hydrologic properties.

In permafrost areas, downward thawing from the surface in the warm season forms the active layer, several centimeters to a couple of meters deep, depending on climatic conditions and soil properties. The annual temperature range is the highest at the soil surface, ranging approximately between –30 °C and +30 °C, and is dampened with depth. In ground with changing volumetric liquid water content due to freezing and thawing processes, the internal energy can change through sensible heat transfer, expressed as a change in temperature, as well as through latent heat transfer, expressed in a change in liquid water or ice content. The freezing and thawing of wet soil is affected by latent heat release due to phase change, which slows the soil warming and cooling.

Fig. 1 The mean annual ground temperature (MAGT, °C) as the modeled mean annual ground temperatures at the top of the permafrost for the Northern Hemisphere at 1 km spatial resolution. The 0°C isotherm is indicated by the boundary between colored and noncolored areas. Adapted from Obu J, Westermann S, Bartsch A et al. (2019) Northern hemisphere permafrost map based on TTOP modelling for 2000–2016 at 1 km² scale. *Earth-Science Reviews* **193**, 299–316. doi: 10.1594/PANGAEA.888600.

Soil thermal properties, i.e., volumetric heat capacity and thermal conductivity, depend on the constituents of the soil, i.e., the volumetric fractions of mineral, organic, liquid water, ice, and air, and their distribution (Fig. 2). The composition of the solid soil constituents changes with depth as determined by the soil stratigraphy. The contents of liquid water and air are variable with both depth and in time due to both thermal and hydrological processes. While the volumetric heat capacity is obtained as the weighted sum of all constituents, the thermal conductivity cannot be calculated easily from the corresponding values of its constituents because their spatial arrangement has a dominant influence.

Permafrost-affected soils are often characterized by a surface organic layer that consists of mostly organic matter. This surface organic layer appears to be one of the most important factors controlling the thermal regime. The thickness of this organic layer can range from a few centimeters to several decimeters, depending on the rates of accumulation and decomposition of plant litter. Often, the soil surface is covered by moss layers. These organic surface layers have a large effect on the thermal and hydrologic processes of the active layer. This is due to the fact that the thermal diffusivity of organic matter is an order of magnitude

Fig. 2 Results of X-ray computed tomography image and laboratory analysis of the same permafrost core, drilled in 2017 in the soil of the Yedoma complex, Lena River Delta, Siberia. Left: Raw image of an X-ray computed tomography of one sample slice (0.005 cm) using computer tomography (1 cm slice = 200 images). The images obtained show different colors based on density differences of the material. Lighter grays indicate higher densities (for example, mineral grains in white), dark gray low densities (for example, gas in black), and light gray medium density (excess ice). Middle: Photograph of same permafrost core at 57 cm depth (below land surface). The composition (organic, mineral, excess, and pores) is the result of standard soil laboratory analysis (thickness of slice: 1.9 cm). Right: Classification of the imaged sample slice (left image) using manual thresholding segmentation of the histogram. This image-based classification cannot resolve the composition of the material but shows a complex spatial arrangement of all the constituents at high resolution. Varying constituents of pore ice and organic and mineral material are thus designated as mixed sediment phases A and B. Figure reproduced from Nitzbon J, Gadylyaev D, Schlüter S, Köhne JM, Grosse G and Boike J (2022) Brief communication: Unravelling the composition and microstructure of a permafrost core using X-ray computed tomography. *The Cryosphere* 16: 3507–3515. doi: 10.5194/tc-16-3507-2022. See further explanation and online video 3D material; Nitzbon J, Gadylyaev D Boike J (2021) *Material Composition in Permafrost Core Through Computer Tomographic Imaging*. smaller than that of mineral soil constituents. In addition, when pores are filled with air, this decreases the soil thermal conductivity. The low thermal conductivity of the surface organic layer creates an effective insulator, decreasing the heat exchange between permafrost and the atmosphere, cooling the soil in the summer (Porada et al., 2016). On the other hand, when saturated, or especially when icy, the thermal conductivity is orders of magnitude higher. From a hydrological perspective, a higher organic matter content increases the soil porosity, affecting the flow and storage of water. The hydraulic conductivity (of peat) ranges across several orders of magnitude between dry and saturated conditions. Including a surface organic layer in earth system models has largely improved their representations of permafrost thermal dynamics (Chadburn et al., 2015).

Permafrost was often regarded as being impermeable to water flow (“aquitard”), but actually water does migrate in frozen soils under thermal and pressure gradients. In soils colder than 0 °C, a certain fraction of liquid water remains in the soil pores because of capillary and adsorption forces, surface effects, and an electrical double layer. As the temperature drops below 0 °C in a porous medium such as soil, the liquid water in the largest voids will freeze. As a consequence, the liquid-ice interface will move into pores with smaller radii, leaving some water in liquid form. For ice and liquid water in thermodynamic equilibrium, a characteristic relationship between soil temperature and liquid water content exists. This relationship depends on the total amount of water present in the material, on the texture of the material (i.e., fine vs. coarse), and on the purity of the water. Thus, freezing of ground and phase change of water occurs gradually over a certain temperature range below the freezing point, in which liquid water and ice coexist. This relationship of the amount of liquid water present at a given subfreezing temperature (soil freezing characteristic curve; SFCC) depends mainly on the share of different constituents in the soil and its texture. To describe the SFCC mathematically, a common assumption is that the freezing of soil can be described in the same way as the drying of soil, with the latter expressed as the soil water retention curve (SWRC). Both empirical formulations, SFCC and SWRC, are implemented in models for the calculation of hydraulic and thermal properties of seasonally freezing soils.

When permafrost degrades, or ground ice thaws, the ground surface will subside due to the volume reduction of ice to water or lateral export of melt water. The opposite process, heave, is the upward displacement of material due to freezing. Soil characteristics are important in terms of the amount of heave and subsidence, such as soil type, grain size distribution, and the availability of water.

Heave and subsidence of the ground surface can offer insight into processes of heat and mass transfer in freezing and thawing soils. The typical seasonal amplitudes are within the range of 20–120 mm (Gruber, 2020). Subsidence can be measured directly, but recent techniques have focused on measurement of permafrost-affected soil displacements from electrical resistivity measurements, differential interferometric synthetic aperture radar (Antonova et al., 2018), and remote sensing. The existence of ice-rich permafrost has substantial implications for thermal and hydrological processes, as well as permafrost stability. Melting of massive ground ice

creates topographic and hydrologic changes, with long-lasting effects and feedbacks on the landscapes and carbon turnover (Nitzbon et al., 2020).

Cryo-pedogenetic processes

The thermal regime of permafrost-affected soils and particularly the cycles of freeze-thaw lead to special cryogenic soil formation processes. These cryo-pedogenetic processes include ice segregation, frost heave and subsidence, up-freezing of coarse fragments, frost sorting, thermal contraction and expansion, and gelifluction. One important effect of these processes—on their own or in combination—is cryoturbation. This term refers to all differential soil movements induced by deep frost penetration and frost action (alternate freezing and thawing) (van Everdingen, 2005). An extensive description of the occurrence and processes of cryoturbated soils is provided by Ping et al., (2015).

Ice segregation is an important frost action process behind many cryo-pedogenetic processes and cryoturbation phenomena. The coexistence of solid and liquid phases of water in freezing soils allows water to flow to the freezing front, where it freezes and can form ice lenses (segregation ice or excess ice). Frost heave of soil occurs when soil water freezes due to the volume expansion during ice nucleation (about 9% increase) and is greatly enhanced where ice lens formation takes place. Ice segregation thus causes differential frost heave, leading to increased heterogeneity of microtopography and soil properties. Over longer time periods, this can also lead to the formation of complex patterned ground. Small-scale thermo-mechanical soil models have been successfully used to simulate the formation of nonsorted circles (Nicolisky et al., 2008). The formation of non-sorted circles depends primarily on water-logged conditions and small-scale vegetation heterogeneities. Furthermore, ice segregation drives movement of coarse fragments (frost-pull or frost-push hypotheses, French, 2017), which in turn can lead to frost sorting and patterned ground formation (Kessler and Werner, 2003). Intensity of ice segregation depends on the frost susceptibility of soil materials, which is a function of the soil's pore size distribution, and the rate of temperature drop during freezing.

Another important process leading to cryoturbation is thermal contraction of frozen ground during rapid cooling in winter. This process leads to the formation of vertical cracks several meters deep, often arranged in polygonal networks. When meltwater runs into these cracks and refreezes, several-millimeter-wide ice veins form. If this process is repeated over many years, massive ice wedges build up. In summer, as the frozen ground in the center of polygons warms and expands, the presence of new ice veins prevents it from returning to its former position. This creates strong compression forces that deform the soil and cause soil material to be thrust over the ice veins/wedges at the polygon rims, as described by Lachenbruch, 1962. The soils of the elevated polygon rims typically show cryoturbation, whereas the soils in the depressed centers do not. If ice bodies contained in permafrost-affected soils thaw, the collapse of previously overlying or adjacent soil materials leads to further forms of cryoturbation.

Cryo-pedogenic processes strongly influence the carbon turnover and sequestration of permafrost-affected soils (Ping et al., 2015). However, small-scale soil heterogeneity affected by cryoturbation is not yet represented in most earth system models, but can be shown to have effects on larger-scale energy, water, and carbon balances (Beer, 2016; Shu et al., 2020).

Hydrology of permafrost-affected soils

At fine spatial scales (i.e., meters), water flow in pathways into and through the active layer and along frozen soil layers can influence soil properties in a number of important ways. In the Arctic, there are unique features of permafrost-affected soils that have variable hydrologic and drainage properties. In particular, cryo-pedogenetic processes that form patterned ground have unique soil-hydrologic processes, such as the seasonal increase of water storage potential along with active layer thaw, which are not present outside the permafrost regions. Water moves through the polygonal tundra landscapes in distinctive ways; for example, water flow occurs along the ring-like shape of the polygon center near the polygon rim (Harp et al., 2021). Polygonal tundra geometries affect water movement, drainage timing and patterns, and the trajectory of formation of taliks, which are unfrozen “windows” through the permafrost. Landscape and climate factors influencing polygonal tundra environments and thermokarst pool development are discussed in more detail in Abolt et al. (2020). At scales beyond the soil column (i.e., roughly tens of meters), hillslope processes become dominant. Recent research findings for hydrology of one-dimensional soil column energy and water balances, albedo, and snow-vegetation interactions are discussed below.

Energy and water balances

Energy and water balances of Arctic permafrost-affected soils are highly seasonal. Water abundance plays a large role for the surface energy balance because of the latent heat flux (Q_E) that is driven by evaporation of water, either by direct evaporation from wet surfaces or by plant transpiration. When Arctic land surface and soil conditions are dry, the sensible heat flux (Q_H) and Q_E are similar, or Q_E might even be larger in arid locations with low relative humidity. In wet tundra environments with open water (e.g., lakes, wet Arctic plain environments) and locations with greater relative humidity, Q_E will be the largest in summer. Soil properties, such as thermal conductivity and porosity, have been found to be the main drivers of ground thaw in these environments. Finally, liquid water is warmer than the frozen soil and it transfers energy with it, leading to the development of conduits of flow, preferential pathways through which water, nutrients, and contaminants may move along and through the soil active layer.

Albedo is an important driver of energy balance in Arctic soils, largely because the amount of light reflected has a strong influence on radiation balances, with different effects for summer and winter. It is one of the primary feedback mechanisms of snow and vegetation in Arctic permafrost-affected soils. Albedo can vary significantly with respect to summer vegetation cover, resulting in more radiation either reflected or absorbed at the ground surface. In the winter, the white and bright snow cover reflects energy, leading to reduced warming of the surface. Snow albedo decreases have been linked to black carbon on snow in Arctic environments (Pu et al., 2021). Fires and changes in surface water extents can interact with albedo signatures during the snow season and result in lowered albedo in the boreal Arctic (Webb et al., 2021).

Snow-vegetation feedbacks

In Arctic environments, water in all its forms interacts closely with vegetation, resulting in impacts to the permafrost-affected soils (e.g., Grünberg et al., 2020). Vegetation, particularly shrubs, causes snow to pile up or accumulate along the margins and within shrub patches in Arctic environments, owing to a number of important factors including topography, vegetation composition (density, height, and presence or absence), and wind. Deeper snow protects the ground surface from penetrating cold temperatures, which can insulate the soil and lead to changes in permafrost condition, such as the development of taliks forming conduits for water, nutrient, and gas fluxes. Shallower snow, on the other hand, leads to reduced insulation of the soil and enhanced downward penetration of cold into the permafrost.

Both snow and vegetation are shifting in the Arctic under climate change impacts, with variable responses to permafrost-affected soils which are, in part, dependent on vegetation type and interactions with snow (Bennett et al., 2022). Shrubs are known to be increasing in the Arctic, resulting in changes to snow albedo in the autumn, leading to snow melt that can form a negative feedback, thereby driving or stabilizing permafrost development (Belke-Brea et al., 2020). Similarly, boreal forest canopies alter the surface energy balance of underlying permafrost by inhibiting more than 90% of the solar radiation and suppressing turbulent heat fluxes (Stünzi et al., 2021a). The loss of boreal forests can lead to an increase in the ground surface temperatures and an increase in the active layer thickness (Stünzi et al., 2021b). On the other hand, both shrub and boreal forests can lead to larger below-canopy snow accumulations and a delay of snow melt, which thermally protects permafrost from cold winter air temperatures (Stünzi et al., 2021a). Overall, reductions in snow cover extent across the Arctic can lead to early snow melt, resulting in shorter snow seasons. Recent findings on the importance of rain-driven permafrost thaw play a substantial role in deepening the active layer via both thermal heat transfer and changing soil thermal conductivity, mechanisms that have been overlooked in past research. Summer precipitation and fires can also interact to variably influence upland and lowland shrub development in the Arctic tundra environments (Chen et al., 2021), leading to enhanced permafrost thaw in disturbed and wetland areas.

Coarse-scale feedbacks on changing permafrost-affected soils to Arctic hydrology

At very coarse scales, the hydrology of Arctic permafrost-affected soils can impact global climate through the release of carbon dioxide, methane, and other greenhouse gasses owing to increased thawing of permafrost and deepening of active layers. Enhanced atmospheric moisture in the Arctic can cause increased runoff from thawing permafrost-affected soils, leading to increased runoff to the Arctic Ocean. However, at these coarse scales, it is difficult to understand impacts because the tools that we utilize to study them (i.e., earth system models) may not include the physical processes, such as thermodynamics of the permafrost, vegetation dynamics, biogeochemistry, and subgrid scale snow processes. Additionally, some of these processes are still not well understood, for example, the effects of warming-induced vegetation changes on soil organic carbon turnover. Dynamic vegetation model simulations by Zhang et al. (2013) showed that positive feedbacks on climate warming, for example, reduced snow-season albedo through tree-line advance and shrub expansion may dominate over negative feedbacks, such as increased carbon sequestration in plants and soils. Newer earth system models incorporate these dynamics for Arctic systems, which are in development, testing, and validation phases (<https://ngee-arctic.ornl.gov>; <https://arcticinterface.org>; <https://e3sm.org>).

Gas transport

Permafrost-affected soils and sediments are often rich in organic matter, and biogenic mineralization of this organic matter leads to the release of greenhouse gasses, CO₂ and CH₄, into the soil pore space. Microbial production of CO₂ and CH₄ increases with temperature and is greater in thawed than in frozen soils, yet production continues at low rates even in frozen soils at temperatures as low as −16 °C (Panikov and Dedysh, 2000; Rivkina et al., 2004). Soil gasses exist in the soil pore space either as free gas or dissolved in the thawed or frozen pore water solution. CH₄ can also occur in permafrost as clathrate hydrates. The theoretical stability depth of methane clathrate hydrate in permafrost regions is about 200 m; however, meta-stable methane hydrates have been found in ice-rich permafrost at considerably lower depths (Rivkina et al., 2001; Chuvilin et al., 2018; Dallimore and Collett, 1995).

Gasses are transported within the soils by diffusion or advection. Diffusion of gasses is more efficient in air than in liquid water (order of magnitude of diffusivity ratio: 10⁴); gas diffusion in ice is even less efficient than in liquid water (order of magnitude of diffusivity ratio: 10²). Advective gas transport can be driven by free gas flow, one important mechanism being the upward migration of gas bubbles (ebullition), or by the flow of pore water solution containing dissolved gasses. Large contents of ice as well as hydrates restrict both diffusive and advective gas migration. Therefore, gasses produced in situ in permafrost-affected soils by organic matter mineralization or transported from deeper gas reservoirs can accumulate below near-to-impermeable ice-bearing

permafrost. Thawing of ground ice can lead to sudden blowouts from gas-filled cavities, which can form pockmarks or even deep craters (Bogoyavlensky et al., 2021).

The active layer of permafrost-affected soils, which thaws in the warm season and allows plant growth, is most dynamic in terms of soil gas production, consumption, and transport. In addition to heterotrophic respiration, autotrophic respiration by roots of vascular plants releases large quantities of CO_2 into the soil pore space. Furthermore, root exudation enhances soil organic matter mineralization both to CO_2 under oxic conditions and to CH_4 and CO_2 under anoxic conditions. The active production of CO_2 and CH_4 in the active layer leads to a seasonal buildup of these gasses, but due to their small distance to the soil surface, and because the soil is unfrozen, gas export from the soil to the atmosphere is efficient. Due to the fast turbulent mixing of emitted gasses in the atmospheric boundary layer, concentration gradients from soil to the atmosphere are steep, fostering diffusive transport. Atmospheric turbulence can also create pressure pumping at the soil surface, leading to advective gas transport out of the soil. Furthermore, pressure pumping as well as shaking of plant structures by wind gusts can trigger the release of soil gas bubbles (Wille et al., 2008). During the refreezing period in the fall, cryostatic pressure buildup in the active layer can lead to squeezing-out and sudden outbursts of CH_4 and CO_2 (Mastepanov et al., 2008).

Vascular plants are essential for the transport of CH_4 from the soil to the atmosphere, in addition to diffusion and ebullition through the soil pore space. Many wetland plants have a unique feature called aerenchyma, which are air-filled tissues found in their leaves, culms, rhizomes, and roots. Aerenchyma allows efficient transport of oxygen from the leaves to the oxygen-deficient soil zones around the roots, while also promoting the transport of CH_4 from the rhizosphere to the atmosphere. This plant-mediated transport can be due merely to enhanced diffusion, but advective transport mechanisms have also been observed; these are driven by pressure gradients within the plant structures.

Arctic warming is expected to increase land-atmosphere fluxes of CO_2 and CH_4 . Thawing will make permafrost more permeable to soil gasses stored in or below the permafrost. Moreover, thawing will mobilize previously frozen organic matter, making it more easily available for the active microbial communities in the expanding active layer soils. But probably the dominant effect of Arctic warming on the greenhouse gas fluxes in permafrost regions will be through the effects on biogenic organic matter decomposition via changes in soil temperature and moisture regimes in active layer soils and in plant productivity and composition (e.g., Olefeldt et al., 2013).

Subsidence, degradation, irreversible processes, and the fate of permafrost

Gradual deepening of the active layer, i.e., “top-down” thawing of permafrost, is the typical way in which thawing proceeds in much of the permafrost region. However, thawing develops differently in terrain that hosts ice-rich permafrost deposits. When ice-rich ground thaws or massive ground ice melts, permafrost loses its stability, and the solid ground material subsides as a consequence. This process is referred to as thermokarst, and it involves the formation of characteristic landforms, such as thermokarst lakes, thermokarst depressions, or thermokarst mounds. Compared to gradual, top-down thawing, thermokarst can induce positive feedbacks, such as water impoundment, causing more rapid thawing of the ground.

In contrast to gradual thaw, this type of thaw is typically not captured by large-scale climate models, as these types of models do not specifically represent permafrost deposits containing excess ice (Koven et al., 2013). One of the few permafrost model studies that considers abrupt thaw processes, including thermokarst lake formation and drainage, shows that these abrupt thaw processes can mobilize large amounts of previously frozen organic carbon in deep permafrost layers during the 21st century (Nitzbon et al., 2020). One reason why thermokarst is not represented in most earth system models is that the process operates at fine spatial scales (meters to hundreds of meters), resulting in land cover spatial heterogeneities which are far below the lateral resolution of coarse-scale models (tens to hundreds of kilometers). Characteristic thermokarst landforms and other patterned ground features in permafrost regions are linked to heterogeneities in many surface and subsurface properties, such as vegetation, microtopography, soil texture, and water and ice content. These fine-scale heterogeneities in turn affect the transport of energy and water over the landscape (i.e., snow redistribution or water fluxes over a polygonal terrain). Numerical modeling using a tiling approach showed that lateral processes and the distribution of excess ice play key roles in the pathways of landscape evolution and permafrost degradation in ice-rich terrain (Nitzbon et al., 2020).

Summary

Degradation (warming and thawing) of Arctic permafrost is an ongoing global phenomenon and this process may be irreversible on shorter than millennial timescales. As permafrost thaws, increasing and deepening heat and water transfer through the active layer and taliks occurs as a result and will mobilize nutrients, carbon, contaminants, and greenhouse gasses. Due to the highly complex combination of permafrost state, hydrology, soil, and vegetation properties, the effects of Arctic warming on energy, water, and carbon fluxes in permafrost landscapes are difficult to predict and remain highly uncertain.

Thermokarst-related processes cause changes in the energy and water balances of ice-rich terrain, which result in substantially larger amounts of projected permafrost degradation and thaw-affected carbon under a warming climate, compared to projections for ice-poor terrain. The role of hydrology (wetting, drying) and the presence of excess ice and thermokarst will likely determine the fate of permafrost.

Abstract

Permafrost and seasonally frozen soil are a dominant feature of cold regions around the world. The ice forming in frozen soil influences the hydrology of cold regions by: (1) reducing soil infiltrability and increasing surface runoff over frozen soil surfaces, (2) forming an impermeable barrier at the top of ice-rich soil and controlling the lateral flow of groundwater, and (3) providing a source of melt water during warm seasons.

Key points

- Soil freeze-thaw processes have a strong influence on soil hydraulic conductivity and infiltrability, and the partitioning of snowmelt into infiltration and runoff.
- Snowmelt infiltration in frozen soil is controlled by macropore networks that are open to flow even when the frozen soil matrix allows little infiltration. The hydrology of cold region is sensitive to agricultural practices that alter the development of macropore networks.
- Permafrost influences the partitioning of surface and subsurface water by limiting storage and flow of water in the ground and promoting storage and flow near and at the ground surface. Near surface flow paths are generally associated with fast travel times and water chemistry reflecting flow through organic rich soil layers.
- Climate-change effects on frozen soil has a large degree of uncertainty due to the complex feedback between soil, vegetation, and snowcover that provides insulation from cold air. A warmer winter (and shorter duration of snowcover) does not necessarily mean shallower soil frost.

Introduction

Permafrost and seasonally frozen soil cover approximately 50% of exposed land surfaces in the Northern Hemisphere (Zhang et al., 2003). In this article ‘cold region’ refers to the region in which snow and frozen soil have substantial effects on hydrological processes. The soil in these regions freezes and thaws in response to cooling and warming of the soil surfaces. Repeated freezing and thawing can influence soil physical, chemical, and biological processes (Hayashi, 2013) and alter soil structure and properties.

The ice forming in pore spaces influences the hydrology of cold regions by: (1) reducing soil infiltrability and increasing surface runoff over frozen soil surfaces, (2) forming an impermeable barrier at the top of ice-rich soil and controlling the lateral flow of groundwater, and (3) providing a source of melt water during warm seasons. The warming of climate will alter the depth and seasonality of soil frost and the thickness and spatial extent of permafrost. This will also affect the hydrology through changes in the three processes mentioned above.

Hydrological processes in seasonally frozen soil

Hydraulic conductivity of frozen soil

The blockage of flow by ice in pore spaces is the primary reason why hydrological processes are sensitive to soil freezing and thawing. Since soil hydraulic conductivity is determined by pore-size distribution and pore connectivity, it is sensitive to which pores are blocked and how. Soil matric potential is negative in the vadose zone meaning that the thermodynamic potential of liquid soil water is lower than that of free water. This results in freezing point depression, whereby soil water remains in the liquid phase at temperatures substantially below 0 °C. Given that the water suspended in smaller soil pores has a lower matric potential, the degree of freezing point depression is also greater. Therefore, ice formation in water-saturated soils starts in the largest water-filled pores. Since the permeability of individual soil pores is proportional to the square of pore diameter, the blockage of largest pores greatly reduces soil hydraulic conductivity.

The relationship between soil temperature, T (°K), and matric potential, μ_m (Pa) is represented by the Clausius-Clapeyron equation (Williams and Smith, 1989, p.190):

$$\frac{d\mu_m}{dT} = \frac{\rho_w L_f}{T} \quad (1)$$

where L_f (J kg⁻¹) is the latent heat of fusion, and ρ_w (kg m⁻³) is the density of liquid water. For example, the soil matric potential corresponding to -0.1 °C is roughly equal to -120 kPa. Therefore, the water in unsaturated soil at $\mu_m = -120$ kPa (or matric potential head of -12 m) does not freeze until the temperature drops below -0.1 °C (see Fig. 1 for an example). A theoretical pore diameter corresponding to -120 kPa is approximately 2 μm, implying that pores larger than a few microns are filled with air (Fig. 2a) (Mohammed et al., 2018).

These large, air-filled pores can transmit the infiltrating water sourced by rain or snowmelt. However, if the soil temperature is sufficiently low, the infiltrating water will freeze in pores, and the ice forming in these pores will block the flow of water and prevent further infiltration (Fig. 2c). Therefore, the history of repeated freezing and thawing and the timing of infiltration are important for the partitioning of snowmelt water into infiltration and surface runoff (Fig. 3b).

In addition to downward infiltration, liquid water in soil pores can move upward from a deeper zone to the freezing front (Fig. 3a), which is the boundary between partially frozen soil above and unfrozen soil below, driven by the matric potential gradient generated by the low potential of frozen soil (see above). When the unsaturated hydraulic conductivity of unfrozen soil is negligible, due to the small water content, water vapor plays a substantial role in the upward transfer of water from a deeper, warmer soil to the freezing front driven by the vapor pressure gradient. The upward flow of soil water to the freezing front from the water table (Fig. 3a) can cause the latter to recede during the frozen period in shallow unconfined aquifers (Ireson et al., 2013).

Role of macropores in frozen-soil infiltration

The theoretical framework presented above is useful for understanding the flow through frozen soil matrix. However, most soils in vegetated areas have macropores formed by decaying plant roots, animal burrows, and other processes. These macropores remain dry during freeze-thaw cycles and provide open conduits for infiltration. Relatively fast movement of liquid water in macropores can cause a thermal disequilibrium, whereby the temperature of water flowing through macropores can be substantially higher than the temperature of soil matrix. Depending on the rate of water inputs from the surface (e.g., snowmelt rate) and flow velocity, macropore networks in frozen soil can remain open and allow unrestricted infiltration (Fig. 2c). However, macropore networks

Fig. 1 Relation between liquid water content and temperature for silt loam soil for different total water contents (WC). The soil is saturated (i.e. no air in pore spaces) for the curve of total WC = 0.37. Other curves show the cases in which the soil is unsaturated prior to freezing (Watanabe and Wake (2009)).

may have local constrictions, which can slow the water movement and provide sufficient time for freezing and the blockage of macropore networks (Watanabe and Kugisaki, 2017). Therefore, the presence of macropore network does not necessarily cause sustained infiltration at a high rate in soils subjected to large temperature swings due to diurnal warming/cooling or a mid-winter warm event (e.g., foehn) followed by a cold period.

Land-use effects on frozen soil infiltrability

Given that macropore networks have a strong influence on the infiltrability of frozen soil, it is important to understand the factors controlling the formation and destruction of soil macropores. In general inversion tillage can improve the soil structure over a short time frame (e.g., one growing season) but it destroys macropores and prevent the development of well-connected macropore networks. As a result, cropped fields under conventional tillage typically have smaller frozen soil infiltrability compared with undisturbed grasslands having the same soil texture (Hayashi, 2013). Therefore, conventionally tilled fields tend to generate greater amounts of snowmelt runoff over frozen soil than undisturbed grasslands.

Zero-tillage and continuous cropping practices allow the soil to preserve macropore networks, thereby reducing the amount of snowmelt runoff. On the other hand, grasslands subjected to animal grazing may be affected by compaction by animals and may have less developed macropore networks compared to natural grasslands. Therefore, the contrast in snowmelt runoff generation between cropped fields under zero-till and grazed grasslands is smaller than between conventionally tilled fields and undisturbed grasslands.

Effects of snowcover on infiltration and runoff

Snowcover has a strong influence on frozen-soil processes by providing thermal insulation of soil surfaces and releasing snowmelt water. Soil freezing and thawing is controlled by energy fluxes and storage in a complex system consisting of snowpack, plant canopy and crop residue, and soil. The thickness of snowpack and the height and density of plant canopy are spatially heterogeneous, which can result in a substantial spatial variability in soil freezing and thawing processes (Fig. 3a). Snow accumulation and melt processes are influenced by topography and land-use practices such as crop management, grazing, and tree harvesting in forests. Therefore, the variability in topography and land use can have a strong influence on soil freezing/thawing and snowmelt infiltration and runoff processes at various scales ranging from field plots (e.g., 1 m) to a landscape (e.g., 10^2 – 10^3 m).

Spatial scale of runoff generation

Heterogeneous distribution of snowpack and frozen soil results in a high spatial variability of snowmelt runoff generation within a catchment. Therefore, some areas of a catchment may have frozen soils generating runoff and other areas may be unfrozen and accommodate the infiltration of snowmelt runoff transferred from frozen areas (Fig. 3b). Depending on the sizes and connectivity of runoff-generating areas within the catchment, frozen soil may not have a measurable influence on catchment-scale runoff. Therefore, it is important to consider spatial scales for understanding the effects of frozen soil on hydrological processes.

For example, the Northern Great Plains of North America is subjected to seasonal soil frost up to 1–1.5 m in depth and has a high density of topographically closed depressions ranging in size from 10^2 to 10^4 m². Snowmelt runoff generated over frozen soils in the catchment of these depressions are retained until it starts to spill over the edge of the depression. A large fraction of snowmelt water collected in the depression infiltrates and recharges local groundwater (i.e. depression-focused groundwater recharge). As a result, catchment-scale runoff measured in stream gauging stations is much smaller than local-scale runoff generated over frozen grounds. Similar scale-dependent snowmelt runoff has been observed in forested slopes, where the canopy density controls snowpack thickness, which in turn controls the extent of frozen soil and snowmelt runoff (Stähli, 2005).

Hydrological processes in permafrost regions

Impact of permafrost on the distribution of water

In permafrost regions, which cover approximately 25% of the northern hemisphere landmass, at least some of the ground material is perennially frozen, although unfrozen water may also exist within permafrost due to freezing point depression caused by soil matric potential (Eq. 1) or by high solute concentration. The active layer is the layer of ground above permafrost which thaws and refreezes seasonally as temperature fluctuates between annual maximum and minimum (Fig. 4a). Permafrost is defined as a perennially cryotic zone (Fig. 4a), meaning temperature $\leq 0^\circ\text{C}$ for two or more consecutive years, which is different from a perennially frozen zone (French, 2018, p.72). Therefore, the boundary between the active layer and permafrost may be ambiguous in some cases (gray zone in Fig. 4a). Under a warming climate, temperature profiles can deviate substantially from the equilibrium profile resulting in a perennially non-cryotic ($T > 0^\circ\text{C}$) zone above permafrost, referred to as talik (Fig. 4b). Fig. 4c and d demonstrate the difference in seasonal progression of soil freezing and thawing in cases with and without talik. The active layer typically reaches a maximum thickness ranging from decimeters to a few meters depending on local climate and ground thermal properties. In regions with continuous permafrost, where at least 90% of the ground surface is underlain by permafrost, the active

(b) Temperature-depth profile under a warming condition depicting the development of talik between the active layer and permafrost. (c) Schematic diagram showing seasonal progression of freezing and thawing of the active layer directly overlying permafrost. (d) Seasonal progression of freezing and thawing under a warmer condition depicting the presence of talik between the active layer and permafrost.

Fig. 5 Hydrological features and landforms in a landscape with continuous permafrost (left side of river) and discontinuous permafrost (right side of river).

layer constitutes the main aquifer of consideration for most hydrological concerns. In the active layer the water table is perched on top of the frost table which continuously thaws deeper over the summer season (Fig. 5).

Percolation from the active layer into deeper aquifers below the permafrost is restricted by low permeability frozen ground, which leads to an abundance of wetlands and lakes in many lowland permafrost areas. Polygonal terrain is common in lowland tundra areas and forms by repeated infiltration of water into thermal contraction cracks over hundreds to thousands of years, creating a polygonal pattern of ice wedges below the tundra surface (Fig. 5) (Liljedahl et al., 2016). Due to the massive ice content in ice wedges, the ground above them is raised above the surrounding tundra and water is often ponded in the center of so-called low centered polygons. When ice wedges degrade, the raised polygon rims turn into troughs leading to redistribution of water into the rims of so-called high center polygons. In high-center polygonal terrain, the troughs provide connected drainage paths which may lead to less ponding of surface water and more runoff, compared to low-center polygonal terrain (Liljedahl et al., 2016). The perched water table and abundance of wetlands, such as ice wedge polygons, can contribute to relatively high evapotranspiration

rates in some permafrost areas, as much water is stored near or at the ground surface (Sjöberg et al., 2021). Evaporation tends to dominate over transpiration, although few published studies have been focused on the partitioning of evapotranspiration in permafrost areas (Young-Robertson et al., 2018). With decreasing cover of permafrost into the discontinuous and sporadic permafrost regions the number of connections between aquifers increase and the regional partitioning of surface water and groundwater is less affected by the presence of permafrost.

Taliks, springs, and frost mounds

Taliks are important storages and conduits for (liquid) groundwater (Fig. 5). Taliks can be non-cryotic ($> 0^{\circ}\text{C}$) or cryotic ($\leq 0^{\circ}\text{C}$). Non-cryotic taliks are often found below water bodies, such as lakes, streams, and wetlands, or on relatively warmer south-facing slopes (in the northern hemisphere) or in locations with thick insulating snow cover which. Cryotic taliks are kept unfrozen due to a lowering of the freezing point of water. Cryopegs are perhaps the most common type of cryotic taliks and are defined as layers of ground that remain unfrozen at temperatures below 0°C due to large concentrations of dissolved solids. They are often found in coastal permafrost areas. Open taliks penetrate the permafrost completely, while closed taliks are contained above or within the permafrost (Woo, 2012). Open taliks allow for discharge of groundwater from below the permafrost to the ground surface and thereby the formation of springs. During winter, the freezing of discharging groundwater can lead to build-up of icings (German *aufeis*, Russian *naled*), for example in stream beds and near springs. Icings typically range in size from a few square meters to tens of square kilometers depending on the supply of water (Ensom et al., 2020).

Where ice blocks the discharge of groundwater through the ground surface, mounds can form from the build-up of ice from freezing groundwater below the surface (Woo, 2012). Pingos are perennial frost mounds that can reach heights above 100 m and are classified into open system or closed system types (Fig. 5) (Yoshikawa and Kane, 2021). Open system pingos receive water through underlying taliks connecting them to the subpermafrost aquifer. Closed system pingoes are found on top of closed taliks in the continuous permafrost zone, typically in drained lake beds. As permafrost aggrades after lake drainage, water in the closed talik is pressurized and expelled into the pingo ice core. Distinct types of frost mounds, namely palsas and peat plateaus, are found in peatlands. These landforms, which are typically less than a few meters high, are formed by ice segregation and often create locally drained islands in otherwise waterlogged peatlands. While closed system pingos are typically found in continuous permafrost areas, open system pingos are common in the discontinuous permafrost areas, and palsas and peat plateaus are common features near the climatic margin of permafrost in sporadic and isolated permafrost zones.

Seasonality, travel times, and flow paths

The seasonal development of the active layer contributes to high seasonal variability in water flow paths and travel times. The seasonal deepening of the frost table in the active layer can lead to a pronounced transmissivity feedback in permafrost areas, as flow paths in the early summer go through near surface material with high hydraulic conductivity (Carey and Woo, 2001). Such shallow flow paths are associated with short travel times, and as the summer progresses and the frost table thaws deeper, flow paths may deepen, and travel times may grow longer. The seasonal development of flow paths also results in seasonally variable water chemistry in streams draining permafrost areas. In the active layer, groundwater flow may move predominantly in the organic topsoil in early summer but move into deeper mineral soils with thawing over the summer and the water chemistry tends to reflect such changes (O'Donnell et al., 2021). Water in subpermafrost aquifers in continuous permafrost areas tends to move slowly and can be several thousand years old and often has large concentrations of dissolved solids.

Catchment-scale effects of permafrost

Streams that drain permafrost regions are commonly characterized as flashy. The presence of permafrost generally leads to very low streamflow during the winter season due to limited groundwater inflow and solid precipitation (snow). The peak flow during spring freshet is in contrast very high, reflecting the shallow and rapid flow paths during this season. Near surface water is also drained through water tracks which form stream-like drainage networks in many continuous permafrost regions. While there is no formal definition of water tracks, they are commonly referred to as local to regional linear features with high soil moisture, sometimes including overland flow, and a thick active layer (Trochim et al., 2016). By increasing the landscape hydrologic connectivity, they have important impact on the drainage response of permafrost catchments. They are easily distinguishable in tundra landscapes by relatively lush vegetation. Just like seasonal progression of thaw can be reflected in water chemistry, the catchment-scale extent of permafrost may also impact the chemistry of streams. In a catchment with continuous permafrost much water moves through organic-rich near surface flow paths while with less permafrost more water moves through mineral soil layers. For example, high concentrations of dissolved organic carbon (DOC) in stream water can be seen as an indicator of permafrost whereas higher levels of weathering products in stream water may indicate less permafrost in the catchment.

Effects of climate change on soil hydrology in cold regions

Climate-change effects on the hydrology of seasonally frozen soil

A rise in winter temperature will generally increase the rain-to-snow ratio of winter precipitation and shorten the period of snowcover. While there is a fair degree of confidence in this prediction over the global scale, the effects of warming on soil frost will likely have substantial regional- and local-scale variabilities. This is because the complex interplay between temperature and precipitation affects snow accumulation and melt processes, which in turn affects soil freezing and thawing through thermal insulation, or lack thereof, by snowcover (Iwata et al., 2010).

Field experiments in cold regions around the world have unequivocally shown that the removal of snowcover lowers soil temperature and increases frost depths. In contrast, a thickening snowcover results in warmer soil temperatures but a shallower frost depth (Fig. 3a). Therefore, if the warming causes frequent snowcover depletion during warm spells followed by cold spells, it will increase the frost depth instead of decreasing it. Such a scenario may increase or decrease snowmelt runoff, depending on the amount, intensity, and timing of snowmelt; and the infiltrability of near-surface soil (see below).
